BULLETIN OF THE GEOLOGICAL SOCIETY OF NORFOLK

No. 27

CONTENTS INCLUDE :

"Lyelliana"

DOUBLE ISSUE
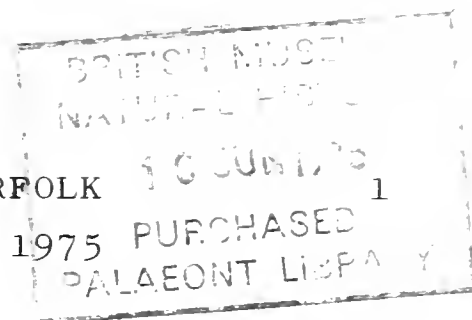

EDITORIAL

Our President, Hywel Evans, gave us an illustrated view of some of his recent research into the tills of the Bawsey district, near King's Lynn. We are now happy to print a summary of that talk and invite comment and rejoinders on the content. Hywel has also started an annual lecture for the society at King's Lynn with our western members in mind, a noteworthy innovation which we wish well.

This edition is a double edition for a number of reasons. Our production editor, Brian Funnell, will be away at the time when the autumn edition would normally go to press and also the impending vast increase in postal charges can be minimised by combining two editions. I hope this meets with members' approval.

Our numerous contributions this time cover the county from east to west from several points of view. We have also included some 'Lyelliana' to mark the Centenary of the death of Sir Charles Lyell, a not infrequent visitor to Norfolk, and observer of its geology.

Five contributors have started work on the 'New Geology of Norfolk' with sections to be issued as separate booklets as the manuscripts become available. These will then be bound into a single volume on completion of the series.

Bulletin No. 28 will be issued in April 1976. Contributions should be sent to me as soon as possible, and

2

to be certain of inclusion, no later than 30 September 1975. Will contributors please note that manuscripts are acceptable in legible handwriting, although typewritten copy is preferred. In either case it would be a great help if details of capitalisation, underlining, punctuation, etc., in the headings and references (particularly) could conform strictly to those used in the Bulletin. Otherwise publication may be delayed.

Illustrations intended for reproduction without redrawing should be executed in thin, black ink line. Thick lines, close stipple, or patches of black are not acceptable, as these tend to spread in the printing process employed. Original illustrations should, before reproduction, fit into an area of 225 mm by 175 mm; full use should be made of the second (horizontal) dimension, which corresponds to the width of print on the page, but the first (vertical) dimension is an upper limit only. All measurements in metric units, please.

R.S.J.

THE SUB-MESOZOIC FLOOR IN NORFOLK

P.N. CHROSTON* and M. SOLA

Introduction

      The general features of the sub-Mesozoic floor in
Eastern England are well known. In East Anglia the
floor forms part of the London-Brabant Massif and comes
to within 150m of the surface. The overlying Mesozoic
rocks are thin compared to Lincolnshire and to southern
England, and it appears that the Massif has been a
relatively stable area since the late Devonian.

      Various aspects of the geology of the floor have
been discussed by a number of authors. Bullard et al.
(1946) conducted seismic refraction measurements around
Cambridge and reviewed the available borehole data in
the East Anglia region. A contour map of the sub-Permian
floor was included in Kent (1949), and in a later paper,
Kent reviewed the general geology of the sub-Mesozoic
floor in Eastern England (Kent 1968). An account of the
Caledonian igneous rocks in Central and Eastern England
has been given by Le Bas (1972). Recently, an important
contribution has been the production of a map of the sub-
Mesozoic (strictly sub-Upper Permian) geology in southern
Britain by Professor Wills (1973).

      In these and in other papers, however, information
on the geology of the sub-Mesozoic floor of the northern
part of East Anglia is scant, and it is the purpose of
this short article to review additional information now
available. The results of deep boreholes and geophysical
surveys are described, and, as any proper attempt at

* School of Environmental Sciences, University of East
  Anglia, NORWICH NR4 7TJ.

understanding the floor in Norfolk must take account of
information from a much wider area, data from outside
Norfolk is included.

Deep boreholes

Deep boreholes in East Anglia show a variety of
rock types ranging from Precambrian to Permian in age
beneath the Mesozoic cover. In the south-east, boreholes
at Harwich, Sutton and Weeley show steeply dipping rocks
which were deposited as mudstones and siltstones. The
age of the rock is certainly lower Palaeozoic and is
possibly upper Silurian (Bullard et al. 1946). Further
south, in the London area, numerous boreholes have
revealed Palaeozoic rocks. Most of these are Devonian
sediments but a few show Silurian (Wills 1973). In
central Suffolk a boring at Culford shows "a greenish-
grey slaty rock" at 161 m below O.D., beneath Lower
Greensand (Whitaker and Jukes-Brown 1894). It is possibly
comparable to the Palaeozoic rocks found in the bores
around Harwich (Bullard et al. 1946) and is marked as
Silurian on the Tectonic Map of Great Britain (Institute
of Geological Sciences 1966a). At Cambridge, Carboniferous
Limestone was found in bores carried out by the IGS
(Edmunds 1954), and at Soham, to the north-east of
Cambridge, an IGS borehole penetrated Devonian. At Warboys
in Huntingdonshire, a borehole was put down by the
Institute to investigate the cause of distinct gravity
and magnetic anomalies. The borehole penetrated diorite
below Lower Liassic at a depth of 170 m below O.D.
(Institute of Geological Sciences 1966b). Le Bas (1972)
has briefly described the rock and suggests that the
diorite is probably a Caledonian intrusion. Another
IGS borehole close by to the north of the Warboys site,
at Upwood, showed volcanic agglomerate (?Precambrian)
beneath Keuper Marl (Institute of Geological Sciences
1966b), whilst two others, at Huntingdon and Great
Paxton, showed mudstones and siltstones of Llanvirnian

age beneath Lower Lias (Stubblefield 1967, Institute of Geological Sciences 1967).

The the northen part of East Anglia, however, knowledge of the geology of the sub-Mesozoic floor has relied heavily on the two widely spaced and well-known boreholes at Lowestoft and North Creake.

At Lowestoft the borehole, put down for water supply investigations, penetrated dark hard mudstones below Lower Greensand at a depth of 492 m below O.D. (Whitaker 1906). The rocks are generally described as Lower Palaeozoic (see e.g. Wills 1973), but the age is some-what uncertain and indeed it might be younger (Stubblefield 1967).

The North Creake borehole is perhaps one of the most important boreholes in Norfolk. It was carried out in 1946 by the D'Arcy Exploration Company and its position gave critical control to the interpretation of the sub-Mesozoic rocks of the Midlands and East Anglia. At a depth of 733'm ,Bunter sandstone rested on a "dark greenish grey, somewhat sheared tuff" (Kent 1947, p. 12). The rocks resemble the agglomerate or tuff found in Leicestershire and were therefore ascribed to the Precambrian. Deep boreholes between Leicester and North Norfolk at Foston, Sproxton and Glinton have also shown similar rock types beneath the Mesozoic, demonstrating the presence of a ridge, largely of Precambrian rocks, extending between these two areas.

Apart from those described above, other deep bores have been carried out in the last ten years as part of the North Sea oil and gas exploration programme. Although it was well known from the previously established borehole and geophysical data that the thickness of the post-Palaezoic sediments was small, and that the Palaezoic rocks themselves were of doubtful importance in the search, there was always the possibility that gas may be strati-graphically trapped in the Mesozoic succession. Also the wells were important for obtaining information on the

general stratigraphy of the area. New data on the sub-
Mesozoic rocks from seven oil company wells in East
Anglia is given below. The data is based entirely on
the well logs of the companies concerned. Their
locations are shown in Fig. 1.

Fig. 1. Deep boreholes (solid circles), University of
East Anglia seismic refraction lines (open circles),
and depth to the sub-Mesozoic (strictly, sub-Permian)
floor in East Anglia. Contour interval 100 metres.
Key to ages: PC, Precambrian; a-b, Lower Palaeozoic
b^{6-7}, Silurian; c, Devonian; d, Carboniferous.

(i) <u>Little Chishill (Essex)</u>

At a depth of 147 m below O.D. the Mesozoic rocks rested on a maroon mudstone, hard, massive and fossiliferous, with a light grey shaly limestone, hard,and with brachiopods and other fossils. The bedding was virtually horizontal and the rock has been dated as Devonian. The borehole is about 10 km to the south of Cambridge, where the Carboniferous Limestone is known to form the top of the Palaeozoic floor.

(ii) <u>Four Ashes (Suffolk)</u>

Here the floor consts of a dark grey shale with streaks of siltstone at a depth of 217 m below O.D. The shale had a dip of approximately 35°, and it was ascribed to the Devonian.

(iii) <u>Lakenheath (Suffolk)</u>

The Mesozoic rocks rest on a hard grey-green to maroon siltstone. The siltsone has some contorted beds and local fracture planes at a dip of 50°, but the bedding is horizontal.' The depth at the unconformity was 188 m below O.D. Below 210 m the siltstone alternated with a grey hard silty shale. The age is possibly Devonian.

(iv) <u>Ellingham (Attleborough, Norfolk)</u>

This borehole has been included on Professor Wills' fine map (Wills 1973). Rocks of probable Devonian age are found at 309 m below O.D. They consist mainly of a green, hard, massive mudstone with marked fracture planes and a dip of $50-55^{o}$. Beneath 329 m the lithology changes to a dark grey, hard slate.

(v) <u>Saxthorpe (Norfolk)</u>

Beneath a thick Permo-Triassic sequence, Lower Palaeozoic rocks, tentatively dated as Silurian, are found at a depth of 771 m. The borehole penetrated some 162 m of shales, siltstones, mudstones, and fine silty sandstones. A core showed an apparent dip of $30-40^{o}$, with a poorly developed vertical cleavage.

(vi) <u>East Ruston (Norfolk)</u>

East Ruston lies close to the north-east coastline of Norfolk, and some 15 km from Saxthorpe. In this distance there is, however, a dramatic change in the lithology of the Palaeozoic floor. At the bottom of the Permo-Triassic sandstones, and at a depth of 995 m below O.D., a basal conglomerate rests on top of Carboniferous Limestone. About 100 m of this rock is present and it is generally a white to pale-tan, fossiliferous, dolomitic limestone, locally red stained and in places oolitic. In parts, clay and silty shale bands are present. Below 1095 m there is a Lower Carboniferous sandstone and shale unit and this rests on what is possibly Lower Palaeozoic at 1109 m. Some 396 m of this latter rock was penetrated and the lithology appears very similar (from the log description) to the Lower Palaeozoic of the Saxthorpe borehole, being a sequence of shales, mudstone, siltstones and fine sandstones. No palaeontological evidence of the age is available.

(vii) <u>Somerton (Norfolk)</u>

This deep boring also lies close to the coast of north-east Norfolk, and is only some 7 km from the borehole at East Ruston. Beneath Permian sandstone (Rotliegende), at a depth of 978 m below O.D., are 43 m of Barren Red Measures (Carboniferous). These are red and grey clays, siltstones and shales. These follow some 18 m of Lower Westphalian clays above a thick (139 m) dolomitic lime-stone sequence. This is similar to the East Ruston Limestone, being cream, brownish, hard and massive, and fossiliferous. In places mudstone is present, and also traces of fine sandstone. An interesting feature is the extensive mineralization in the upper part of the limestone with galena, pyrites and marcasite being present.

Below the limestone, at a depth of 1180 m, a sequence of sandstones, siltstones and shales extend down to 1370 m below O.D. This and the limestone sequence are known from palaeontological evidence to be Visean (S + D zones).

Below the Carboniferous, a hard blue grey to dark grey
shale and siltstone with slaty cleavage and dips up to
70° was encountered. It was tentatively ascribed to
the Lower Palaeozoic (?Silurian).

Superficially, there does not appear to be any
great difference in lithology between the rocks described
as Lower Palaeozoic and those described as Devonian.
The former (Harwich, Sutton, Weeley, Culford, ?Lowestoft,
Saxthorpe, Somerton) could be described as typically
"geosynclinal", the rocks including fine mudstones, shales
and slates, with thin silt bands. However, the Devonian
rocks from Lakenheath, Four Ashes and Ellingham show
similar lighologies (from the borehole logs) with shales,
and slates and siltstones. The writer has not examined
the cores from the above boreholes, but a detailed
examination might reveal significant differences in
lithology between the Devonian and Lower Palaeozoic rocks.
A quite distinctive lithology is of course found for
the Devonian of Little Chishill, which shows a considerable
amount of limestone (indicating a shallow marine environ-
ment?).

Much of the dating of the borehole data is somewhat
tentative, though Devonian dates appear to give Middle
or Upper Devonian (see Wills 1973). Structurally also
there is no clear division. Although Professor Wills
tentatively describes the pre-Carboniferous geology to
the south-west as "gently folded thin ORS/Dev. on sharply
folded and faulted Lower Palaeozoics" steep dips are found
for both in the boreholes.

The boreholes situated on the north-east Norfolk
coast appear to be at the point where there is extensive
thickening of the Carboniferous sequence into the North
Sea basin. The Carboniferous limestone found at Cambridge
in evidence for an extensive marine transgression at that
time, but the original cover of limestone seems at least
to have been thin and perhaps discontinuous (Kent 1968).

The new borehole data described above suggest some
modification to Professor Wills' map of the sub-Mesozoic

geology. The boreholes at Lakenheath and Four Ashes
show that the Devonian rocks may well extend some way
to the south-west from Attleborough (Ellingham borehole),
and indeed, there may be a virtually complete cover of
Devonian to Soham, with the Lower Palaeozoics of Culford
being surrounded by the younger rock. Also, the borings
at East Ruston and Somerton show Carboniferous rocks
encroaching into the north-east of Norfolk. It should
be stressed however, that the dating of the sub-Mesozoic
rocks in several of the boreholes is somewhat tentative,
and accurate palaeontological dating may result in
significant changes.

Geophysical data

        Geophysical data available and relevant to the
study of the sub-Mesozoic floor in Norfolk includes
gravity and aeromagnetic anomaly maps published by the
Institute of Geological Sciences and seismic refraction
data obtained by members of Cambridge University (Bullard
et al. 1946) and by the University of East Anglia (Sola
1974).

        The seismic refraction experiments carried out by
Bullard et al.(1946) covered an extensive area in the
central part of East Anglia and enabled a contoured map
of depth to the sub-Mesozoic floor to be made. The pro-
gramme of seismic studies being carried out by the
University of East Anglia is aimed at extending the
Cambridge studies into Norfolk, with the eventual object
of producing a more detailed map of depth to the floor
than can be obtained by the boreholes alone. Also, by
analysing the distribution of velocities of the sub-Mesozoic
floor refractor, it is hoped to obtain further information
on the geological nature of the refractor.

        There are certain limitations in the use of the
seismic refraction method in the calculation of depth to
the refractor and the calculated depth may only be
approximate. The IGS boreholes at Wybostan and Soham,
for example, demonstrated the sub-Mesozoic floor to be at
a depth which was less than had been predicted by the

seismic method (Bellerwell, in Stubblefield 1967).
However the difference between predicted and proven
depth in East Anglia appears to be generally small. In
Fig. 1 a contoured surface of depth to the sub-Mesozoic
floor is shown. For the southern part of East Anglia, it
is based largely on the depths from borehole data, but in
the north some provisional University of East Anglia seismic
results have been used.

The velocities of the compressional wave in the
refractor vary fron 3.5 to 6 km. s^{-1}. The high velocities
(6 km. s^{-1}) are found in the north and a correlation with
the Precambrian volcanic rocks is possible. The lowest
velocities (3.5 to 4.5 km. s^{-1}) are found in the Cambridge
area. Carboniferous Limestone has been shown here (Edmunds
1954), but the seismic sites giving the velocities extend
over a fairly wide area, and the Little Chishill borehole
close to them shows Devonian as the refractor. Two seismic
lines in Norfolk (Sola 1974), and a number in N.W. Suffolk
(Bullard et al.1946) show the refractor to have a velocity
of 4.7 - 5.4 km. s^{-1}. Boreholes in the vicinity here
however (Lakenheath, Culford, Four Ashes), show the rock
of the sub-Mesozoic floor to have lithologies comparable
to Little Chishill (mudstones, silts, slates). The reason
for the difference in velocity is not clear. A great
many more seismic lines are required in the region before
even fairly simple maps of the geology based on the
velocities can be made. In particular, some seismic lines
situated in the south-eastern part of East Anglia are
highly desirable.

The aeromagnetic map, reproduced in Fig. 2, potentially
provides considerable information on the sub-surface
geology. A prominent feature is the complex pattern of
magnetic anomalies with steep flanking gradients and
high amplitudes extending in a belt some 30 km wide from
the Wash to Leicester. The steep gradients indicate a
shallow depth to the rock type causing the anomalies. The
most likely source for the anomalies is the Precambrian
volcanics found in the deep boreholes in this area (North

Creake, Glinton, Upwood) but it is quite possible that
Caledonian intrusion (of which Warboys diorite is
evidence) may also contribute. Furthermore, basement
topography in addition to intra-basement magnetization
contrasts can also give rise to magnetic anomalies.
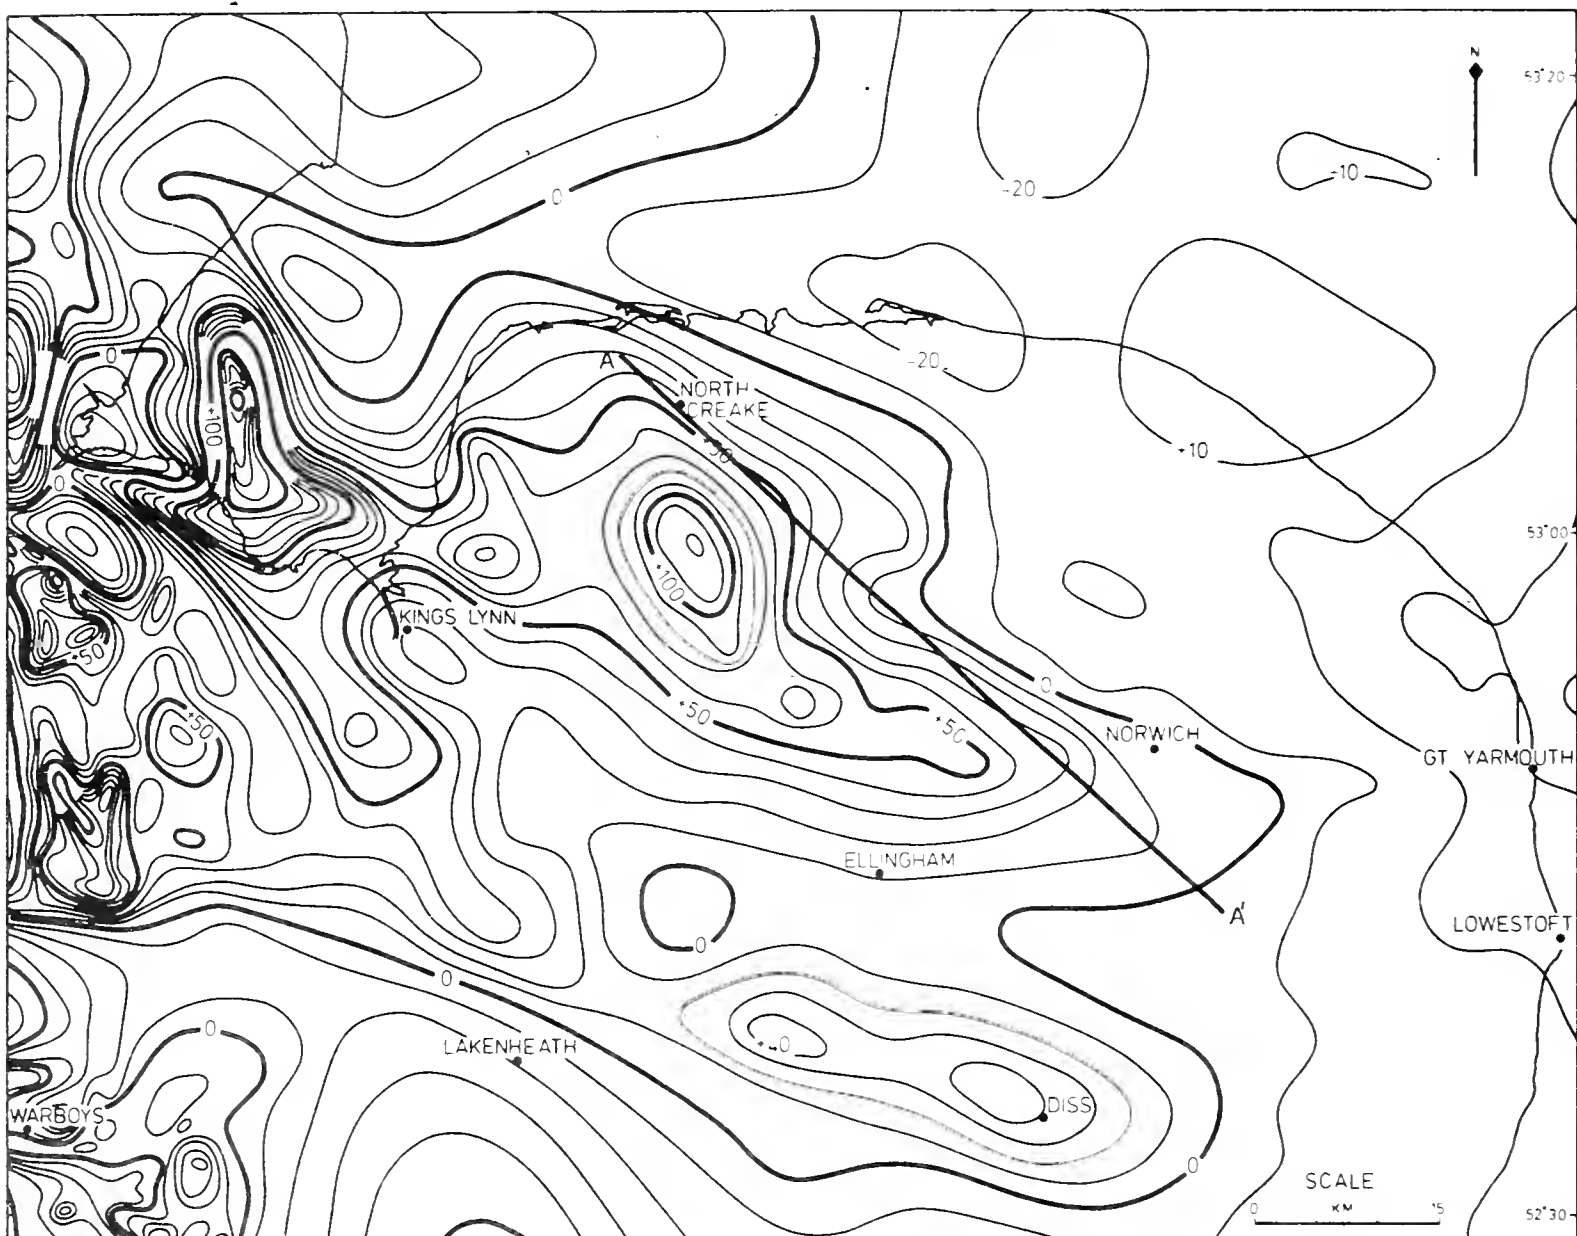

Fig. 2.   Aeromagnetic anomaly map of the northern part
           of East Anglia.   Contour interval 10 gammas.

Although the boreholes in this belt of anomalies have
revealed only the Precambrian, the possibility of
Palaeozoic sediment existing somewhere within the
structurally complex ridge cannot be ruled out. However,
although the pattern of anomalies to the west of the
Wash is complex and difficult to interpret, that over
East Anglia is simpler, the anomalies being of wide extent

and having gentle gradients. This is normally taken
to indicate a deeper magnetic basement which in this
case is assumed to be the Precambrian. Although it is
true that there could be intrusions in the Palaeozoic
strata, they would form distinct magnetic anomalies (as
at Warboys). The Palaeozoic mudstones and siltstones
found in the boreholes in East Anglia can be assumed to
have a negligiable magnetization, and it is possible
that the magnetic basement could be at least 3000 m
(10,000 feet) deep (Kent 1968).

In the north of the area the level of the anomaly
reaches +100 gammas close to North Creake and a prominent
anomaly extends south-east from the Wash towards Norwich.
This can be interpreted as a ridge of Precambrian within
the sub-Mesozoic floor extending and deepening in this
direction. Professor Wills, in his sub-upper Permian
map, has tentatively shown Precambrian exposed on the
floor in this area.

The Mesozoic sediments have a marked density contrast
to the sub-Mesozoic rocks, and with the steady and marked
increase in depth to the floor towards the north coast,
one might expect that the Bouguer anomalies would show
a marked reduction (see Fig. 3). This is partly true in
that across the central part of East Anglia a broad but
positive anomaly with an average value of +3 to +5 mgal,
is found, and overall there is a reduction to the north
coast where values of -1 mgal are typical. However the
picture is somewhat complicated by a distinct 'low' centered
on Guist and Reepham in north-central Norfolk where values
of -6 mgal are observed. Also to the west, around the
Wash, the Bouguer anomaly pattern is complex.

A gravity survey of the Wash by Sola (1974) demon-
strated the presence of a small positive central gravity
anomaly with a relative amplitude of 10 mgal. The anomaly
appears to be an extension of the positive axis to the
south east of Kings Lynn, and over the Wash the gravity
anomaly coincides approximately with the position of a

distinct 200 gamma positive magnetic anomaly. The
interpretation of the gravity and magnetic anomalies in
this western area is difficult. There is, in places, a
close relationship between the gravity and magnetic anom-
alies suggesting a common geological cause. Over the Wash,
interpretation of the anomalies leads to the conclusion
that simple topography of the sub-Mesozoic floor is
insufficient to cause the anomalies and it can be demon-
strated that there must be an intra-basement density and/
or magnetization contrast (Sola 1974). An intrusion is
possible, but the extension of the gravity anomaly to the
south-east suggests some tectonic control.

Fig. 3 Bouger anomaly map of the northern part of East
        Anglia.

It is likely that much of this western area can be similarly interpreted and that both basement topography and the varied geology within the basement can contribute to the anomalies. The problem of interpretation would be eased considerably by detailed information on basement topography, and it is hoped that seismic work in progress in the area of the Wash will be of help in the interpretation of the anomaly there.

In the rest of Norfolk there is not an obvious correlation between the gravity and magnetic anomalies. This is partly to be expected, as the magnetic anomalies will be largely dependent on the topography and character of the Precambrian basement, whilst the gravity anomalies will be affected by the whole of the sub-Mesozoic floor. The construction of models to explain both the anomalies is difficult, as there is little doubt that significant changes in the physical properties may occur within both the Precambrian, and the Palaeozoic sediments in the area. The problem is illustrated in the sketch interpretation of the gravity and magnetic profiles between North Creake and Lowestoft (Fig. 4, from Sola 1974). Using reasonable density contrasts, of 2400 kg m^{-3} for the post-Palaeozoic rocks, 2550 kg m^{-3} for the Palaezoic sediments and 2800 kg m^{-3} for the Precambrian, a wedge of Palaezoic sediment in north Norfolk can be used to explain the gravity low there. However, there is only a fair comparison with the magnetic anomaly profile which suggests that the Precambrian floor in the south-east lies at a much greater depth than that indicated by the gravity profile. With the constraints of known geology and sub-Mesozoic floor topography, there has to be regional variation of the densities and/or magnetizations of the major rock divisions used in the model, in order to satisfy the observed gravity and magnetic anomalies.

An attempt at analysing the major tectonic features of the area, without resort to producing models, was made by Linsser (1968). His technique involved comparing

P.N. Chroston and M. Sola

profiles from the anomaly maps with large families of
computed anomalies due to simple structures at varying
depths. The structure he used was the infinitely thin half
plate (corresponding to a fault). Although the method
produced some interesting tectonic trends, calculation
of depth to the "faults" produced very high values.

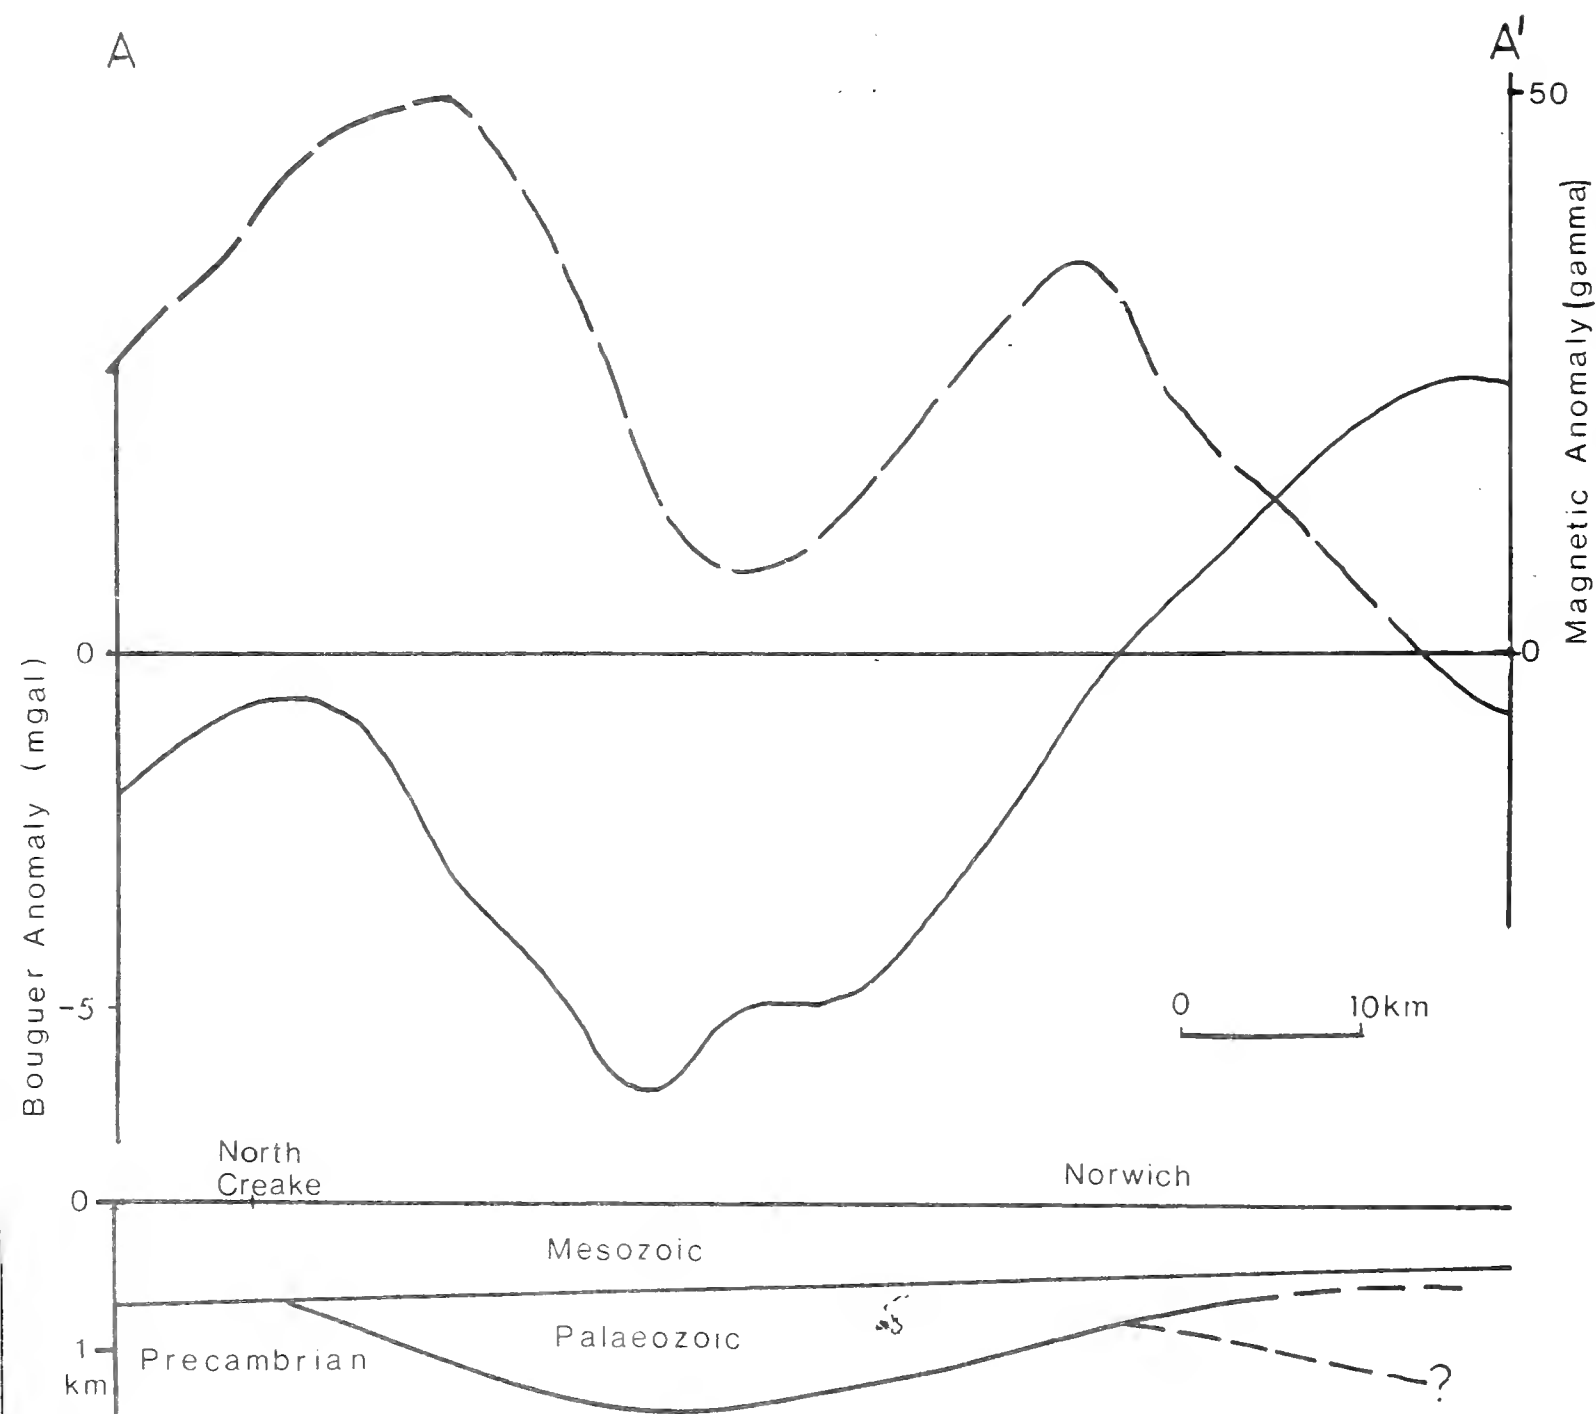

Fig. 4   Bouguer anomaly, total field magnetic anomaly,
         and sketch geological section along the line AA'.
         The lower dashed line in the geological section to
         the south-east indicates the approximate position
         of the Precambrian surface based on the magnetic
         anomaly at this point.

In the Wash for example, depths of over 4 km were obtained, whereas it can be calculated by the method of Bruckshaw and Kunaratham (1963) that the maximum depth to the top of the anomaly causing body is approximately 2.0 km. Depths of over 10 km to the magnetic basement were common in Linsser's analysis over East Anglia and this seems unreasonably high. However, by combining more significant results of such an analysis as this with the simple modelling, it might be possible to delineate areas of particular interest and worthy of more detailed geophysical study.

The new borehole data has provided important new information on the nature of the sub-Mesozoic floor, and it is also of considerable importance as control for the interpretation of the geophysical data. The latter potentially provides the only practical way of examining the gross structure actually within the London-Brabant massif. However, it is clear that the relationship between Bouguer anomaly, magnetic anomaly, seismic velocity and lithology of the floor is complex. Further seismic refraction measurement together with deep drilling in carefully selected areas is needed before the relationships can be fully understood. There is apparently a distinct contrast in compressional wave velocity between the Precambrian volcanics and the Palaeozoic sediments and carefully controlled seismic refraction lines along the axis of the positive magnetic anomaly in Norfolk might well be rewarding.

Norfolk.—The decay of the cliffs of Norfolk and Suffolk is incessant. At Hunstanton, on the north, the undermining of the lower arenaceous beds at the foot of the cliff, causes masses of red and white chalk to be precipitated from above. Between Hunstanton and Weybourne, low hills, or dunes, of blown sand, are formed along the shore, from fifty to sixty feet high. They are composed of dry sand, bound in a compact mass by the long creeping roots of the plant called Marram (*Arundo arenaria*). Such is the present set of the tides, that the harbours of Clay, Wells, and other places are securely defended by these barriers; affording a clear proof that it is not the strength of the material at particular points that determines whether the sea shall be progressive or stationary, but the general contour of the coast.

On the same coast, says Mr. R. C. Taylor, the ancient villages of Shipden, Wimpwell, and Eccles have disappeared; several manors and large portions of neighbouring parishes having, piece after piece, been swallowed up; nor has there been any intermission, from time immemorial, in the ravages of the sea along a line of coast twenty miles in length, in which these places stood.‡ Of Eccles, however, a monument still remains in the ruined tower of the old church. So early as 1605 the inhabitants petitioned James I. for a reduction of taxes, as 300 acres of land, and all their houses, save fourteen, had then been destroyed by the sea. Not one half that number of acres now remains in the parish, and hills of blown sand called 'Marrams' now occupy the site of the houses which were still extant in 1605. When I visited the spot in 1839, I found the tower of the church half buried in the dunes of sand, as represented in the drawing (fig. 43), and twenty three years afterwards my friend the Rev. S. W. King made a sketch from nearly the same spot which is given in fig. 44. In the interval the sand dunes,

Sir Charles LYELL (1797-1875) - extract from his 'Principles of Geology' 1867, pp. 511-2, 513.

THE BASE OF THE CARSTONE AT HUNSTANTON - PART II
R.W. GALLOIS*

Following the successful excavations to examine
the base of the Carstone made at Hunstanton beach on
22nd October 1972 (Gallois 1973), a second field excursion
and series of excavations was organised by Mr. Hamon Le
Strange on 17th June 1973 to try to provide details of
those parts of the Barremian - Albian sequence that
were still in doubt.

Prior to the digging of the first excavation the
nature of the base of the Carstone was. thought to be
relatively simple. The Carstone (probably Lower Albian
in age) was thought to rest with marked unconformity, and
with striking lithological change, on the Snettisham
Clay (Lower Barremian), with a nodule bed at the base
of the Carstone containing derived Lower Greensand
(Lower Aptian) phosphatized ammonites. Much rarer blocks
of very fossiliferous sandy phosphatic ironstone of
Barremian age were also known from Hunstanton beach and
were thought to occur in the same nodule bed as the
derived Aptian fauna, the two types of nodule testifying
to the former presence in Norfolk of a much thicker
pre-Carstone Cretaceous sequence than can now be seen.

The 1972 excavations showed that this interpretation
was much oversimplified; the fossiliferous nodule bed
at the base of the Carstone was by no means as continuous
as had been imagined and the Carstone was underlain by
about 1.5 metres of very sandy oolitic pebbly clay.
This clay was lithologically similar to parts of the
Roach of Lincolnshire (probably Middle and Upper Barremian)
and quite unlike the Snettisham Clay. The pebbly clay
was underlain by very fine-grained sands, and separated

* Institute of Geological Sciences, LONDON, SW7. Published
     by permission of the Director.

from them by an erosion surface. The sands yielded a
few indigenous sandy phosphatic ironstone concretions
which contained pieces of wood and a few shells, including
an ammonite fragment of Barremian affinities.

The purpose of the new excavations was to obtain
further information about the nature of the contact of
the pebbly clay and the fine-grained sands; the indigenous
and/or derived faunas of the pebbly clay and the source of
the very fossiliferous phosphatic ironstone of Barremian
age.

Results

Four trenches were dug with a JCB 3C seaward of the
outer Carstone reef and close to excavations (3) and (4)
of 1972 (Gallois 1973, Fig.1). Two of these trenches
(at TF 67144156 and TF 67074156) were abandoned due to
inflow of water from the overlying beach sands and gravels.
In this respect future excavators may be interested to
note that the more inviting parts of the beach (those
which dry out at low tide) are underlain by waterlogged
gravelly sands, whereas those areas where the clays
are close to the surface remain permanently wet.
Successful excavations were made at TF 67124152 and
TF 67054168.

The combined results of the 1972 and 1973 excavations
are summarised below and in Fig. 1. It should be noted
that the bed numbers referred to here differ from those
in Gallois 1973. This is because, in the later
excavations, it became clear that Beds (2) and (3) of
the 1972 excavations were part of a single bed of
variable lithology.

The sequence can be summarised as follows:-
RECENT: Beach sand, gravelly in places   0.30 to 0.50m
CARSTONE: Bed (4): Fine-grained, orange-
             brown, pebbly, oxidised and rotted,
             ferruginous soft sandstone; ghosts
             of limonite ooliths throughout; very

vation.

rare phosphatic nodules as below;
passage at base into   0.03m

Bed (3): Sandstone, as above but very
pebbly and including dark brown gener-
ally well rounded phosphatic nodules
(up to 0.1m across but mostly 0.02
to 0.03m), some with worn specimens
of Lower Aptian ammonites, including
Cheloniceras, Dufrenoyia, Prodeshay-
esites, and Tropaeum: larger
unfossiliferous phosphatic nodules
(up to 0.12m across) also occur, mostly
of burrow fill shape. In some sections
phosphatic nodules are extremely rare,
in others they occur in clusters;
Bed (3) is locally less pebbly and
indistinguishable from Bed (4).
Ferruginous seepage at base   0.15 to 0.20m

? CARSTONE: Bed (2):   Dark grey and greenish
                grey oolitic (chamosite, largely
                oxidised to limonite) pebbly clay,
                sandy in part, intensely burrow-
                mottled and varying both laterally
                and vertically in composition with
                pebbles and ooliths concentrated
                in bands generally 0.15 to 0.20m
                thick; pebbles (mostly iron-stained
                quartz) lithologically identical to
                those of Beds (3) and (4). Large
                well rounded nodules of very foss-
                iliferous sandy phosphatic ironstone
                (the 'iron-grit' nodules of Keeping
                1883, p.33) were collected from near
                the top of this bed in the 1930s
                (e.g. British Museum(Natural History)
                specimen Nos. C35512 and C35238).

Thickness variable; very irregular
sharp base with burrow fills of
fine and medium-grained greenish
yellow sand (Carstone lithology)
extending down to 0.5m below the
junction; irregularities of up to
0.15m observed in 2m length of
junction   1.00 to 1.50m

ROACH: Bed (1): Pale and medium grey
intensely burrow-mottled sands and
very fine-grained clayey sands;
traces of cross-bedding and burrow-
mottling. Fragments of coalified
wood scattered throughout. Lines of
nodules occur at 0.4m and 1.0m
below the top of the bed. The upper
nodules are very widely spaced: only
two were obtained from about 6 metres
of trenching. These nodules are up to
0.2m across, rounded, irregular and
burrow fill shapes, composed of dark
brown phosphatic ironstone containing
many sand grains, and crowded with moulds
of small bivalves and rarer brachiopods,
gastropods and ammonites. Bits of coalified
wood are also common. Their lithology and
fauna is identical to that of the 'iron-grit'
nodules from Bed (2); they differ only
from the latter in that they are less
well-rounded and, on their outer surfaces,
they have retained traces of the cross-
bedding and burrow- mottling of the sands.
The lower nodules in Bed (1) are probably
only slightly less widely spaced than
the upper nodules: their matrix and
occurrence is similar to that of the

upper nodules, but they are much less
fossiliferous. Small pyrite concretions
occur in association with them. Similar
faunas, including ?<u>Paracrioceras</u> , occur
in the nodules at both levels. Base of
bed not seen.   1.5m

Bed (1) is clearly the source of the 'iron-grit'
nodules of Bed (2); the fauna of these nodules is part
of the indigenous fauna of the Bed (1) sands. The fauna
has been described by Casey (1961, p. 571) as including
'Barremian ammonites of the genus <u>Paracrioceras</u>'. The
fauna from the upper nodules of Bed (1) from the 1973
excavation has been described by Morter (1975, p.   )
as being similar to that of part of the Roach of
Lincolnshire and probably of Middle Barremian age.

A similar lithological sequence to the above, but
without nodule bed or macrofauna,was recorded in the
Institute's Hunstanton Borehole (TF 68574078). In
this borehole, the sands correlated with Bed (1) of the
beach excavations (Gallois 1973, Fig.2) form part
of a complex sequence of sands, clays and pebbly oolitic
clays which can be lithologically matched with the
Roach of Lincolnshire. The faunal evidence form the
new excavations confirms this correlation.

The new excavations have also provided additional
information about the variable nature of Bed (2) and
about its erosional contact on Bed (1). It now seems
very likely that Bed (2) is a basal clayey bed of the
Carstone, possibly of limited local extent. Elsewhere
in Norfolk the basal beds of the Carstone have rarely
been exposed and their lithology may well be variable.
At present, exposures at Leziate Sand Pits (TF 684194)
show the basal beds to be of typical Carstone lithology
(ferruginous sandstone) whilst those at Blackborough
End (TF 677144) are of soft uncemented fine-grained sands.

If Bed (2) is part of the Carstone then the possibility exists that any future excavations might yield indigenous ammonites, and thereby prove beyond all doubt the age of the Carstone at Hunstanton.

or stationary. As the tide rises eight feet at Lowestoff, and sixteen at Cromer, it becomes a question whether in the course of four or five centuries its mean level at any given point on this eastern coast may vary sufficiently to explain the present position of the ruined church at Eccles relatively to high-water mark, but I am not aware that we have any recorded data for confirming or invalidating such an hypothesis.

A BARREMIAN FAUNA FROM EXCAVATIONS AT HUNSTANTON BEACH

A.A. MORTER*

The fauna from some s.andy phosphatic ironstone nodules
(the upper line of nodules of Bed 1 of Gallois 1975, Fig.
1), obtained from excavations at Hunstanton beach, is
described. The fossils are preserved largely in the
form of external moulds and steinkerns, with some original
shell material present. Much of the material is fairly
well preserved, although in some cases replacement of
the shell has resulted in the loss of ornament on the
exterior shell moulds.

The fauna is varied and includes brachiopods,
scaphopods, gastropods, bivalves, and ammonites, the
bivalves being by far the most abundant, both in number
and variety. Wood fragments are also common.

The following fauna was recorded: specimens have been
registered in the Institute of Geological Sciences
Collections under Nos. Zr 9731 to 9770.

Brachiopoda	Rhynchonella parkhillensis Owen and Thurrell
	terebratelloid
Scaphopoda	Antalis sp.
Gastropoda	Tressarolax sp.
	cf. 'Trochus' stillei Wollemann
	small gastropods indet.
Bivalvia	Acesta aff. longa (F.A. Roemer):
	?sp. nov. (mytiliform)
	'Anomia' sp.: probably Paranomia laevigata (J de C Sowerby)
	Astarte sp.

                    Chlamys cf. aptiensis (d'Orbigny) [Syn.,
                             Chlamys robinaldina Auctt]
                    Entolium sp.
                    Freiastarte cf. subcostata (d'Orbigny)
                    Limatula cf. tombeckiana (d'Orbigny)
                    Mulletia mulleti (Deshayes)
                    'Nuculana' sp.
                    Oxytoma pectinatum (J de C Sowerby)
                    Parmicorbula striatula (J de C Sowerby)
                    Resatrix sp.
                    Teredolites in wood with contained
                                      Terebrimya sp.
                    Thetis minor J de C Sowerby

Cephalopoda   ?Paracrioceras sp.
               non-heteromorph ammonite, fragment only
               ?desmoceratid ammonite, early whorls only

    Many of the forms are long ranging and it is difficult
to assign a precise age to the fauna. The most comparable
fauna is that of the lower parts of the Roach of Lincoln-
shire, generally accepted as Barremian in age. Several
of the bivalves have Aptian affinities; but such
affinities are typical of Middle and Upper Barremian
faunas in general, eg. the faunas described by Gillet
(1921) from Wassy (Haute Marne) in the eastern part of
the Paris Basin. Attention can also be drawn to the
marked similarities in lithologies at the level in the
Barremian between such widely separated outcrops as
Wassy, Salzgitter in West Germany (Michael 1967) and
Hunstanton.

    The beach nodules, which are characterised by
abundant Parmicorbula striatula, were not represented
in the stratigraphically equivalent, sparsely fossili-
ferous clayey sands of the Hunstanton Borehole (Gallois
1973, Fig.2). However, the nodules are faunally similar

to a lower stratigraphical level in the Hunstanton
Borehole where this species also occurs in abundance.
This lower level is presumed to correlate with the
Roach stone of the Lincolnshire succession as defined
by Swinnerton (1935). The occurrence of Rhynchonella
parkhillensis in the nodules, only previously recorded
from the Roach Stone of Lincolnshire (Owen & Thurrell
1968), supports a correlation within the Roach sequence.

The absence in the nodules of Corbula isocardiae-
formis indicates on the basis of unpublished borehole
information, a level younger than the Snettisham Clay
and its lateral equivalent the Upper Tealby Clay, which
has been dated by Kaye and Barker (1966) on ostracod
evidence, and on belemnite evidence by Swinnerton (1935)
and Rawson (1972) as Lower Barremian.

The ammonites in the nodules are all incomplete,
but the occurrence of ?Paracrioceras which ranges in
Germany from the uppermost Hauterivian to the top
Middle Barremian (Michael 1967, p. 137) is not at
variance with a Middle Barremian age, i.e. post proven
Lower Barremian, for the nodule fauna.

FIELD MEETING TO BRAMERTON, NEAR NORWICH,
14-15 SEPTEMBER 1974.
P.G. CAMBRIDGE*

Introduction

This was the first meeting of the Society to take
place on more than one day, the object being to excavate
an important geological site. Blake's Pit, Bramerton,
(TG 301063) was chosen for several reasons, not the least
of which was the fact that the incoherent sands are
fairly easy to excavate! It was hoped to produce a
measureable section, which would remain accessible for
some time, and above all to expose the base of the section.
The Crag at this point is known to rest on Chalk, but
the exact height above river level and the precise zone
of the Chalk were unknown. It was assumed that this was
the Scrobicularia Pit of early authors, but since this
species was not found in the exposed upper beds in the pit,
there was some doubt. In all twenty-two members and
friends took part over the two days, and almost all the aims
of the 'dig' were achieved. Samples of the Chalk were
collected, but unfortunately no fossils were found which
would establish the age of the Chalk at this point.

History of the Section

Mention has been made of 'Blake's Pit', or the
Scrobicularia Pit in several of the old memoirs. Shells
were stated to occur in patches throughout the section
and Scrobicularia plana was common, but no section was
given. The Common Pit, nearby, was described in some
detail and was subsequently re-excavated and described
by Funnell (1961) who studied the Foraminifera and
divided the Norwich Crag at Bramerton into three horizons.
The Crag of the area has been considered typical of the
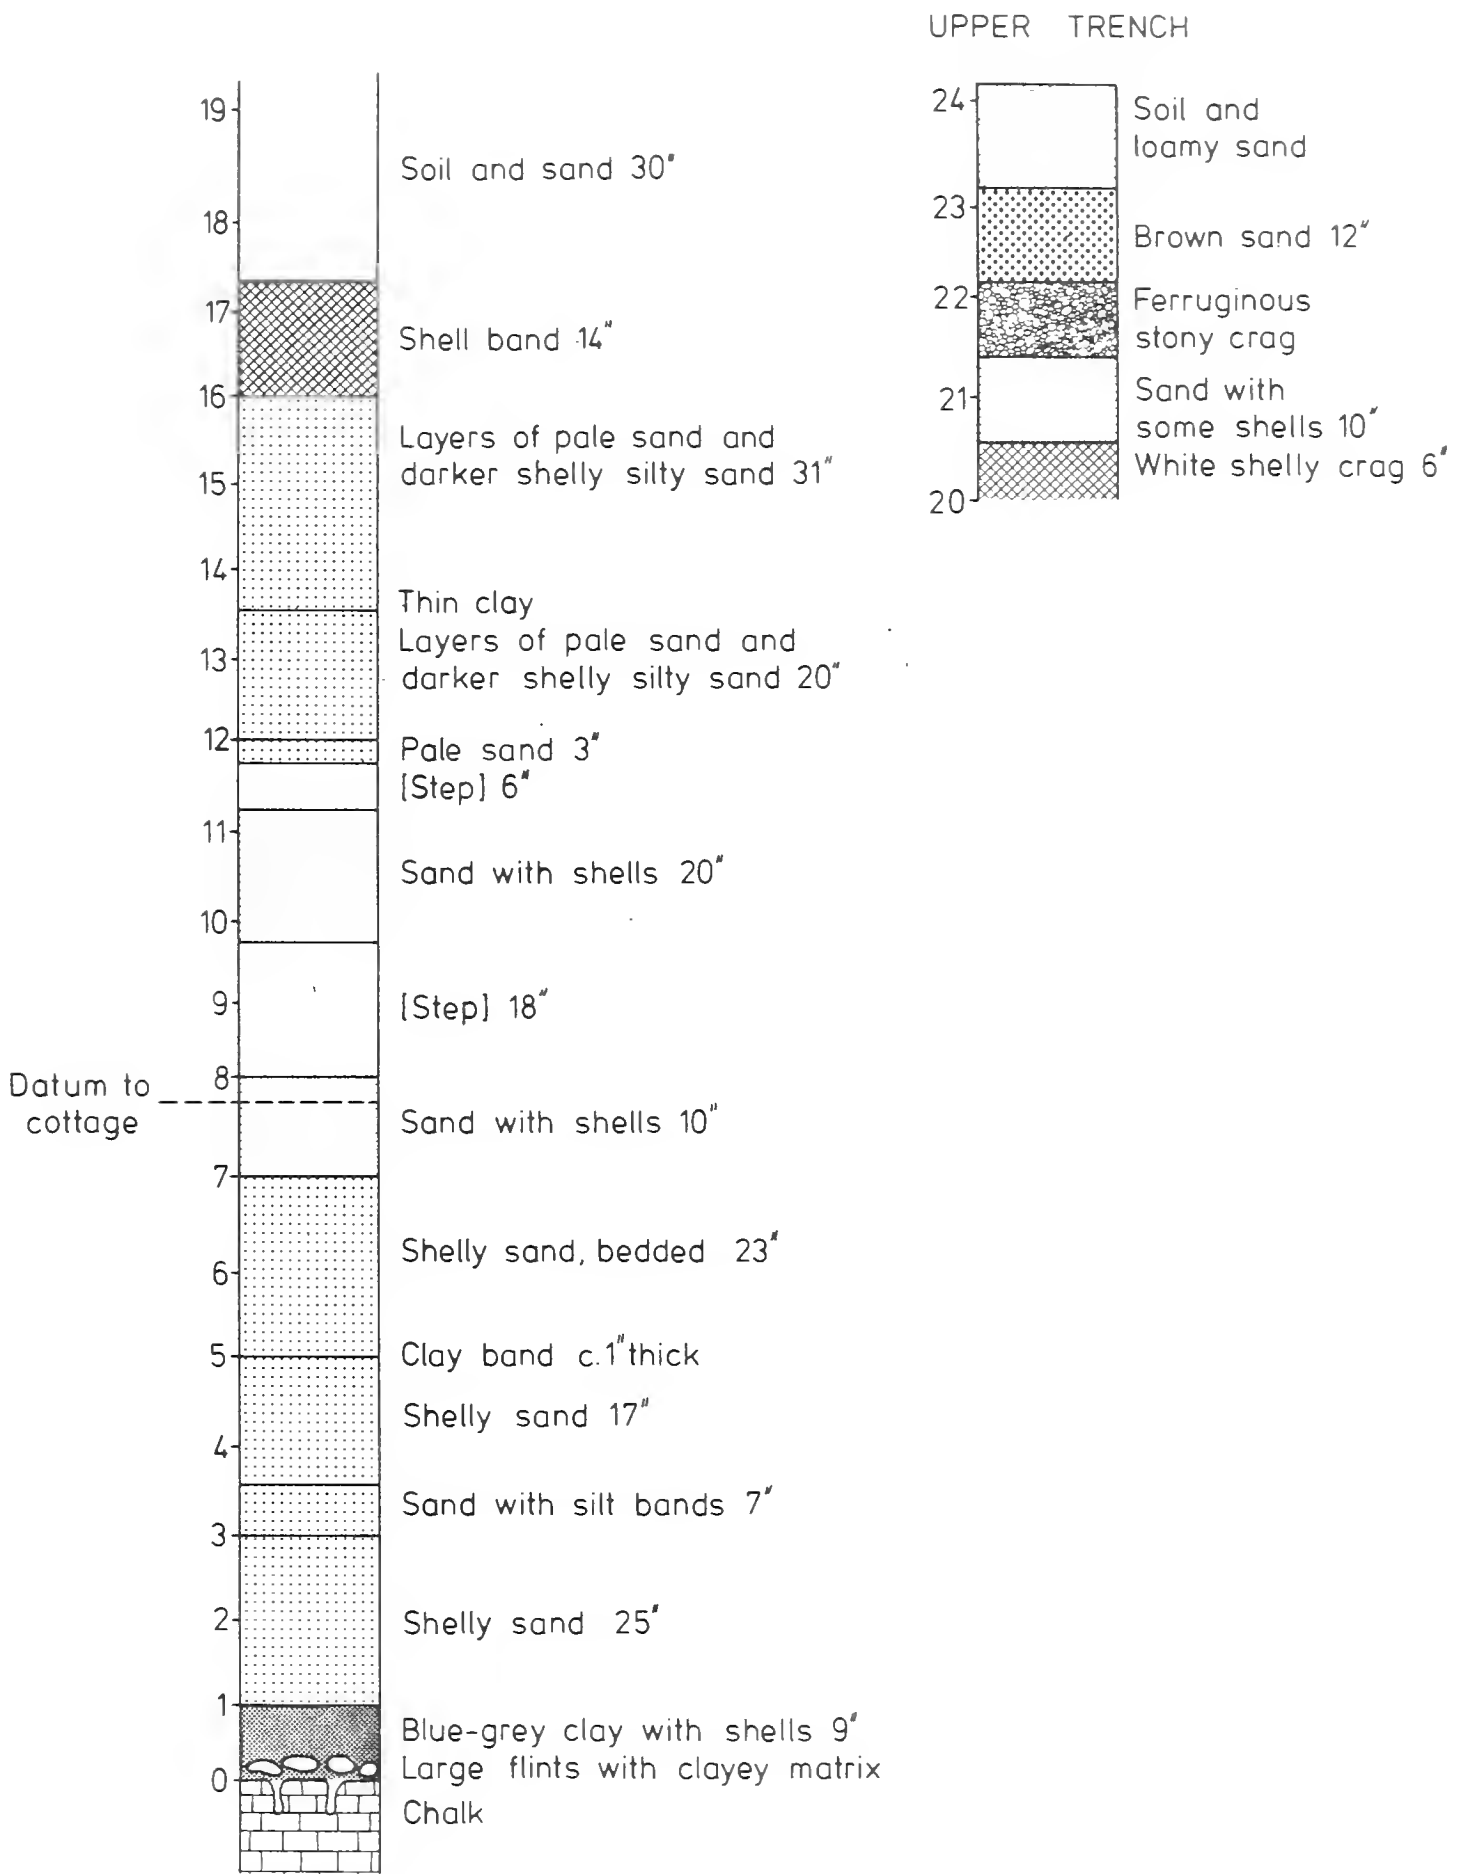

*258 Bluebell Road, NORWICH.

'Norwich Crag' facies of the Icenian of F.W. Harmer,
and in general is recorded as an Upper and Lower Shell
Bed, with more or less unfossiliferous sands between,
the whole resting on a Stone Bed on the surface of the
Chalk. So far the Crag at Bramerton has not been fitted
into the series of palynological zones established by
West(1961) and others , and it is hoped that clay samples
taken during the 1974 meeting will yield a useful pollen
series.

The pit stands close to the river and truncates
a ridge between two of the small dry valleys which indent
the river valley sides at frequent intervals in this
vicinity.

Description of the Section (Fig. 1)

No fossils were noted in the Chalk at the base, but
a large flint was excavated. The surface of the Chalk
has minor irregularities and is stained slightly brownish
by iron oxide. It is penetrated by numerous small,
rather irregular cavities or fissures, usually tapering
downwards, often turning at right angles, sometimes
expanding or branching. At the surface the fissures
are marked by rather irregular hollows, and the average
penetration into the Chalk is about 70mm. Small, dark-brown
nodules occur in the cavities in a matrix of the over-
lying Crag, and these may be phosphatic. One or two
typical flask-shaped burrows of bivalves were seen
(probably Zirphaea sp).

The Stone Bed consists of medium sized flints, the
flatter examples being horizontally bedded; many of the flints
are   heavily corroded by subaerial weathering, and
showing no signs of rounding of sharp edges or chatter
marks. The matrix is a greenish, silty clay with shell
fragments, and the flints are stained a dark, greenish
colour. Apart from flint the only other constituents
were a few of the small dark nodules (10mm) and some
larger ironstone or phosphatic nodules with empty crypts

FIG. 1

of Pholad shells penetrating from all directions.

The Stone Bed is followed by a series of sands with shells and shell fragments with occasional thin seams of clay. These sands are noticeably more shelly towards the base while near the upper part there are beds without any visible shell remains.

At the top of the section (the only part visible for many years) is a bed of extremely shelly sand, showing up as a light-coloured band, resting on non-shelly sand. In this Upper Shell Bed the valves of lamellibranchs lie in layers with the convex surface uppermost. Macoma, Mya, Spisula and Cardium are the most common species. The gastropods Nucella and Littorina are abundant. Most of the common shells are unworn and occur in all stages of growth, but usually do not have an epifauna, although marks of polyzoans are sometimes seen on the shells and detached valves of barnacles are abundant. All the shells are partially decalcified and tend to be fragile. Small tabular fragments of black peaty material are common, the sand is coarser and occasional pebbles occur. The upper part of this Shell Bed shows somewhat apparent reworking, the shells occurring in patches and being more worn, the colour darker and pebbles forming small bands. Fragments of bones are commoner in the upper pebbly patches.

The Upper Shell Bed is followed by brown sands and ferruginous stony beds similar to those seen elsewhere above the Crag. At this point the section reached the brow of the hill and further sections would have entailed a new trench among well established trees.

Since the section is in the form of two narrow trenches lateral variation is not known, and because of the considerable lateral variation, which is a usual feature of the Icenian Beds, the section examined can only be assumed to be typical. In general the section agrees with that given by Funnell (1961) for the Bramerton Common pit, with the Upper Shell Bed of Blake's Pit

equating with the shell bed at the top of horizon BII.
Unfortunately the foraminiferal horizons have not been
established for Blake's Pit and the mollusca are not
well recorded at Bramerton. Common. However Norton (1967)
has recorded 'Littorina littorea var. carinata' from BII
and this further suggests a correlation between the two
shell beds. Special importance is attributed to this
Upper Shell Bed by the present author because of unusual
features in the fauna and its possible use as a strati-
graphical marker in the area.

Interpretation of the Section

Since it has not yet been possible to study all the
material collected at Blake's Pit in detail some of the
following can only be tentative suggestions. However,
the author has examined a considerable bulk of material
from the upper part of the pit. What can be called the
'background fauna' of the Icenian is very similar in
most sections, and indeed, apart from the extinct forms,
bears considerable resemblance to the modern fauna of
the southern North Sea. It is the rarer forms which
probably give more information on conditions during the
Icenian. Non-marine shells occur in many of the Icenian
exposures and when eventually studied should give some
insight into conditions on the nearby terrestrial surface;
they will not be subject to the vagaries of marine currents
as are the marine molluscs. However, sampling of small
quantities of material would probably not produce any
of these important forms.

The unconformity between the Chalk and the Crag
represents a gap of at least seventy million years. It
seems likely that during at least part of the Tertiary the
area was dry land. The shape and condition of the flints
in the Stone Bed at Bramerton suggest a long period of
weathering and erosion of the Chalk surface. I have been
unable to match the small irregular fissures (Fig.2) in
the Chalk surface with any marine organisms. Further,

the large pholad borings, cut through the fissures and
must therefore be subsequent. It is suggested that the
fissures were a terrestrial solution feature, perhaps
formed by roots of plants. During the Icenian trans-
gression the earlier stages may have been the formation
of a series of drowned valleys, rather like those at
present seen in Suffolk and Essex, with small clear
rivers or streams originally occupying the valleys. The
fine basal material, the lack of wear on the eroded flints,
and the presence of examples of Mytilus and Yoldia with
joined valves in the basal bed point to quiet deposition.
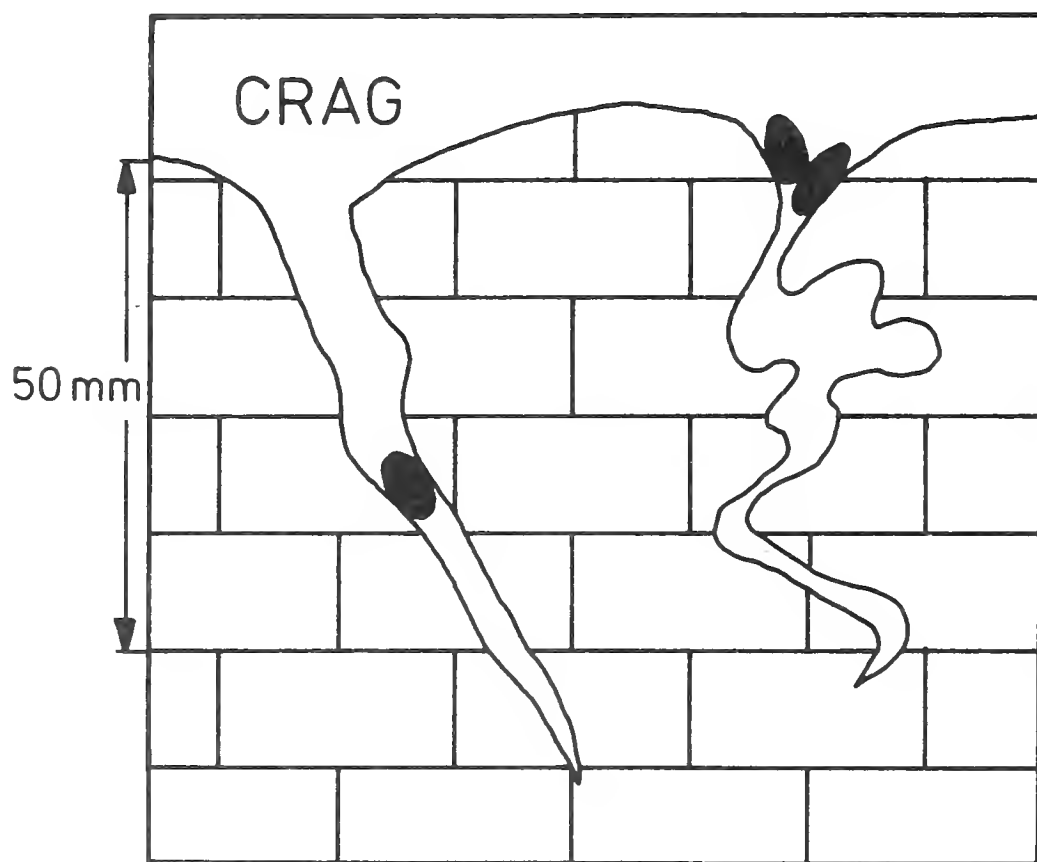

Fig.2 Diagram of fissures
in the chalk surface

The abundance of mammalian remains lying on the Stone
Bed in the Norwich area, coupled with their fragmentary
nature and the mineralisation of many, but not all, of
the bones, suggest their derivation from valley gravels
during the marine transgression, when some may have
already been mineralised. Finally the scattered teeth
and bones of small mammals (mice and voles mainly), and
the presence of a fairly large non-marine fauna, would be
consistent with long estuaries with side streams, rather
than open bays or coastline.

     The Shelly Sands above the Stone Bed have only been
lightly sampled, but the fauna contains many small marine
gastropods and apart from <u>Neptunea</u> large shells are not
abundant. Non-marine shells are by no means rare, and
in a sample of about 10 kg about twenty pulmonates were
found, including: the possibly estuarine <u>Ellobium</u>, the
fresh-water <u>Planorbis</u> and <u>Lymnaea</u>, the land snail <u>Vallonia</u>
and at least two other distinct forms of land snails.
The presence of thin seams of clay, small changes in
grain size, and the absence of shells in some of the sands
may be due to changes in current strength, although no
actual examples of oblique current bedding were noted.

     A more obvious change in conditions is immediately
apparent in the Upper Shell Bed. The presence of larger
pebbles, the convex uppermost orientation if bivalves,
etc. point to stronger currents. Yet clearly some of
the material cannot have travelled very far - the fine
crenulations on <u>Nucella</u> are frequently quite unworn, and
juveniles only 2 to 3mm long occur mixed with large adults
of the same species. It is possible that the large bi-
valves were transported to form shell banks on which the
active gastropods such as <u>Nucella</u> and <u>Littorina</u> lived.
The very thin shells of the brachiopod <u>Hemithyris psittacea</u>
may have been attached to heavier shell fragments or
pebbles. Many of the commoner shells in this bed are
abundant on tidal flats and in estuaries today; many are
intertidal.

Perhaps the most unusual feature of this bed is the presence of monstrosities and extreme variations in some of the species. No common factor seems to be apparent. The species affected include the carnivore <u>Nucella</u>, the scavenger <u>Neptunea</u> and the algae browsing <u>Littorina</u>. The distortions take two forms   The first are monstrosities with no immediately apparent cause - compressed, elongated, scalariform, and heavily keeled forms; the second are usually caused by mechanical damage to the shell or to the presence of barnacles growing on the shell close to the suture, sometimes resulting in complete and random dis- location of the whorls, However, it should be noted that even in the case where barnacles are a causative factor, <u>Balanus</u> spp. and <u>Littorina</u> spp. commonly live together at the present day, and such <u>Littorinas</u> seem capable of dealing with such unwanted additions without distortion. It would appear that some other factor reduced the Littorina's ability to deal with the presence of barnacle larvae, and that the barnacles are a secondary factor in this case. It is curious since at the present day <u>Littorina</u> is a genus singularly free from monstrosities. The remainder of the molluscan fauna, which is fairly large, does not show any such tendency to acute variation. The area in which these forms occur is quite small, having been noted only at Bramerton, Postwick Grove and what appears to be reworked Crag in the Glacial Series at the Sewage Works, Whitlingham. It also seems probable that the monstrosities are confined to the the Upper Shell Bed. Distorted coiling of fora- minifera has been recorded by Funnell (1961) from Bramerton and also occurs in Icenian at Thorpe Aldringham in Suffolk. Grossly enlarged fishbones, referred to "<u>Platax</u>", are fairly common in the Upper Shell Bed but are also found at other localities in the Icenian. It is notable that they usually occur in beds which contain many small bone fragments and pebbles, and generally in 'shell bands'. The Upper Shell Bed at Bramerton has also yielded examples of <u>Viviparus</u> <u>medius</u>, <u>Pisidium</u> and a number of land shells, as well as vole

teeth and remains of other small mammals and fish,
especially in the uppermost part of the shell bed which
has a reworked appearance. The rather more pebbly bands
at the top of the shell bed have also yielded a few
derivative fossils. The presence of flint moulds of
belemnite alveoli, and derived Chalk fossils is easily
explained. Fragments of Oxfordian ammonites and a piece
of crinoidal limestone less easily so. Unlike the Red
Crag which contains a large derived fauna from the Eocene,
derived Tertiary fossils seem unknown in the Norwich Crag,
although the Crag sands transgress over the London Clay
from the east. Probably this is due to the Icenian area
being more sheltered. Two fragments of the polyzoan
Metrarabdotos moniliferum were found in the sample from
the lower shelly sands of Blake's pit and since the species
does not seem to be known later than the Pliocene, except
as a derivative, these specimens may have come from
earlier Crags, especially as they are only a few millimetres
long.

     As elsewhere in the Norwich area, the sandy, shelly
Norwich Crag is succeeded by a pebbly, ferruginous series,
and decalcified sands. It is possible these may have
been originally fossiliferous and subsequently suffered
decalcification, reduction of the contained iron, etc.,
or they may represent high energy shallow water or beach
conditions, or possibly have been reworked during the
regressive stage of the Icenian cycle. In none of the
cases can the shore line have been far to the west,
probably somewhere in the region of the present 150 foot
contour.

     The question of the temperature changes in the
Icenian is a difficult one. The foraminiferal sequence
of Bramerton Common has been interpreted as a steady
cooling ending in very cold conditions. Some of the marine
shells of the Upper Shell Bed are at present indicative
of high latitudes, such as Hemithyris psittacea,
Boreoscala, Macoma calcarea; while others, such as

Calyptraea chinensis are at present more southern. Many
bivalves show great tolerance to temperature changes;
for example Arctica islandica occurs in the warm Miocene
and Pliocene, is abundant in most of the Crag beds and
equally abundant in the cold Clyde Beds. The non-marine
shells would seem to indicate a temperate land surface.
A clay sample from the upper part of Blake's pit contained
some pollen, not too well preserved, in which Pinus
predominated, suggesting a cooler phase, probably from the
BII horizon, but the sample was insufficient to make any
definite statement. It is hoped that a study of the pollen
and the mollusca of the lower part of the section will
eventually yield further information.

Palaeontology

        Faunal lists have been published in the literature
(Taylor 1871, etc., Reid 1890, Woodward 1881, etc.) for
the area, though much of the nomenclature is now out of
date. Only certain forms of special interest are here
mentioned.

Littorina spp. Examples in all stages of growth are
abundant, often with the colour bands well-preserved.
Both L. littorea and L. rudis (s.l.) are present, but
since the taxonomic status of the modern species is in
doubt it was felt best to group the fossil examples
together. The variation in the group was checked by
passing a 100 kg sample from the Upper Shell Bed through
a $1/4$ inch sieve. Juveniles were thus lost. All adults
were examined for variation and the following figures
obtained:

Normal shells		556 examples
Minor variations	79	
Gross monstrosities	90	
Totals	169 (23%)	556 (77%)

In the lower shelly sands 'rudis' seems more common than
'littorea' and no monstrosities have been noted so far.
Nucella lapillus (Linné). Both adults and juveniles
occur and examples are at least twice as abundant as

Littorina . Most are a thin shelled form, with occasional
slight distortion of the whorls, and large apertures,
and show very little sign of wear. Low spired, thick,
small examples are rare and usually worn; a few are
denticulate within the mouth. The variation seems to
fall within that of the modern form. Some examples
have the whorls slightly distorted by juvenile barnacles.
Monstrosities occur, e.g. monstrosity angulata Woodward,
but much more rarely than among the Littorina specimens. Anyone
interested in these monstrosities should see the figures
in Wood (1848-82) and Harmer (1914-25). Harmer's
figure of Neptunea despecta var. pumilio is actually a
monstrous Nucella lapillus.

Neptunea spp. Several species are found in the Crags.
This genus entered the North Sea in late Pliocene times
from the Northern Pacific. The first forms were usually
strongly carinate and were mistakenly referred to N.
despecta by Harmer. Later, in the early Pleistocene, a
smoother form appeared and was referred to N. antiqua.
Both forms continue throughout the Crags and were difficult
to separate owing to the presence of intermediate forms.
Strauch (1972) referred both forms to a new species
N. lyratodespecta which was strongly ribbed, and the
smoother variety to a subspecies striata (Sowerby). Some
modern conchologists prefer to consider both as forms
of N. antiqua. At Blake's pit the Neptunea specimens
in the lower part are finely ribbed and referred to
N. lyratodespecta striata. The examples in the Upper
Shell Bed are mostly those figured by Harmer as var.
curtispira and var. decemcostata (not Say). Both would
appear to be extreme variations or monstrosities of
N. lyratodespecta. A second species N. contraria, also
reached the North Sea in Upper Pliocene times and is
abundant in the Scaldisian and the Red Crag but rare in
the Icenian. An example was found in the Upper Shell Bed
during the dig, the example lacking the typical ribbing
of the species, probably due to wear.

Fish remains.   These are common in the Upper Shell Bed,
including indeterminate vertebrae, dermal ossicles of
Raja clavata, and vertebrae and bones refered by Agassiz
to Platax woodwardii, on account of the swollen appearance
of the bones (hyperosteosis). The Platicidae, a group
of recent Indo-Pacific fishes, show indiscriminate
swellings, in the bones, apparently not of pathological
nature. However, it seems somewhat unlikely that a
tropical fish genus should appear in the North Sea
during the Icenian only. Study of the bones suggested
that they may not all belong to the same species. Certain
of the bones have a different colour and appearance;
these particular bones are also found in deposits in the West
Schelde, Netherlands, but with no sign of the elongate
vertebrae and 'butterfly bones' which were included
in Agassiz' species. A comparison with modern North Sea
fishes showed a close resemblance to the cleithrum, a
bone from the skull of a gadoid fish. Since large
otoliths, referable to the cod, Gadus morrhua, are
occasionally found in the Icenian, it seems probable that
the bones mentioned belong to cod. The remaining elongate
vertebrae and 'butterfly bones' are left in 'Platax'
woodwardi for the time-being until a better indentity
can be established. It is interesting that distorted
fish bones occur in the Upper Shell Bed together with
various molluscan monstrosities, but the combination
is probably accidental since these bones occur in a number
of localities (Covehithe Warren, Easton Bavents, Thorpe
Aldringham, Broome, Bramerton, Whitlingham, Thorpe,
Weybourne) although they only appear at certain horizons,
usually associated with shell beds, and coarse material.

Notes on the Section (Fig. 1)

     A narrow trench (c.1 metre) was dug on the left hand
side of the pit from the top of the section to a short
distance below the top of the Chalk. A second section,
a little to the west of the first, was measured and cleared

to a depth of six feet. A datum point was made, to the
eaves of a near-by cottage, and all measurements referred
to this. At a later date it is hoped to survey an
absolute level above OD. The Upper Shell Bed was not
at the same absolute level in the two trenches and appears
to follow the curve of the top of the ridge. Whether
this is due to irregularities in the Shell Bed or to
cambering on the ridge side is not known.

FOSSIL ICE-WEDGE POLYGONS AT CORTON, SUFFOLK

K. GARDNER* and R.G. WEST[1]

In January 1971 a scour at Corton Cliffs (Fig. 1)
re-exposed the Cromer Forest Bed Series in the upper
part of the beach. The section here is well-known
through the cliff-section and description of J.H. Blake
(1884, 1890), but exposures have been rare since then,
and indeed are unlikely to occur again, as the recently-
built sea defences have led to a permanent build-up of
the beach.

The sequence at the cliff-base is as follows:

Brown boulder clay (Lower Boulder Clay, North
Sea Drift, Norwich Brickearth)

Cromer Forest Bed Series
{
Laminated grey silt and sand up to 2 m thickness

Wood peat and coarse detritus mud up to 0.25 m
thickness

Grey-blue clay (Rootlet Bed)
}

The Rootlet Bed is a marsh clay, and the wood peat
and detritus mud reflect a higher fresh-water level
with rich organic deposition. A marine transgression
followed, depositing inorganic tidal sediments. Finally
the area was overrun with the ice which deposited the
boulder clay. The palaeontological content of the Forest
Bed Series at Corton indicates a correlation of the
three horizons to a period within the Cromerian temperate
stage (type site at West Runton).

The scour in 1971 revealed a plan view of ice-wedge
casts. They are mapped in Figure 3, with an example in

*   The Denes High School, LOWESTOFT.

1   Sub-department of Quaternary Research, Botany School,
     Downing Street, CAMBRIDGE CB2 3EA.
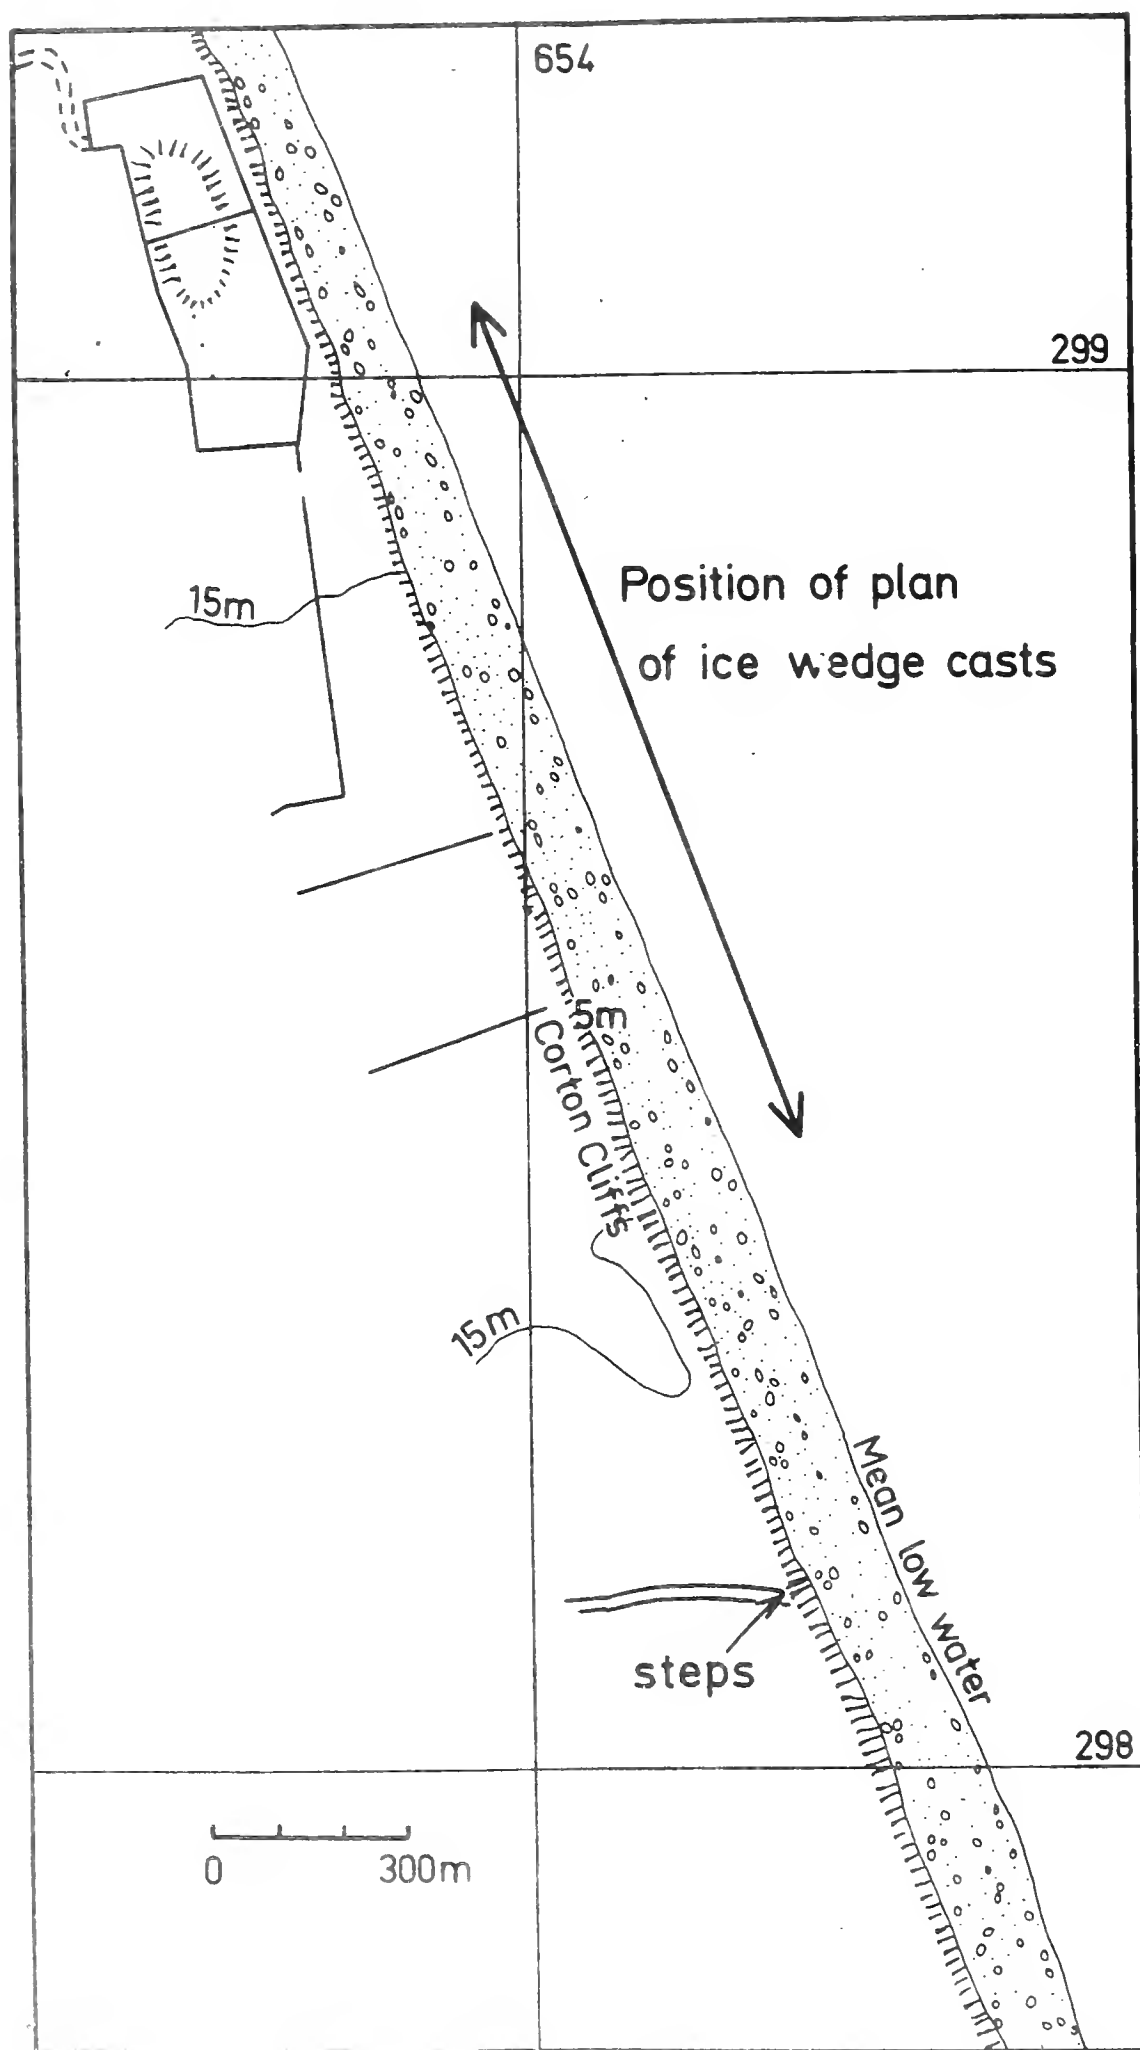

Fig. 1   Map of Corton Cliffs, showing position of polygon
          exposure.

Figure 4.   Figure 3 also shows the position of two small basin-like features which may have originated by the collapse of ground-ice.

The ice-wedge casts penetrate the Rootlet Bed to depths of up to 1 metre, and are rendered conspicuous by the ferruginous oxidation of the clay along their flanks.   The oxidation is at a maximum along the centre line of the wedges and merges outwards in each direction, with varying degrees of abruptness, to the unweathered grey clay.   Figure 2 shows two sections, five metres apart along the most northerly wedge observed, drawn when the wedges were exposed in 1961.
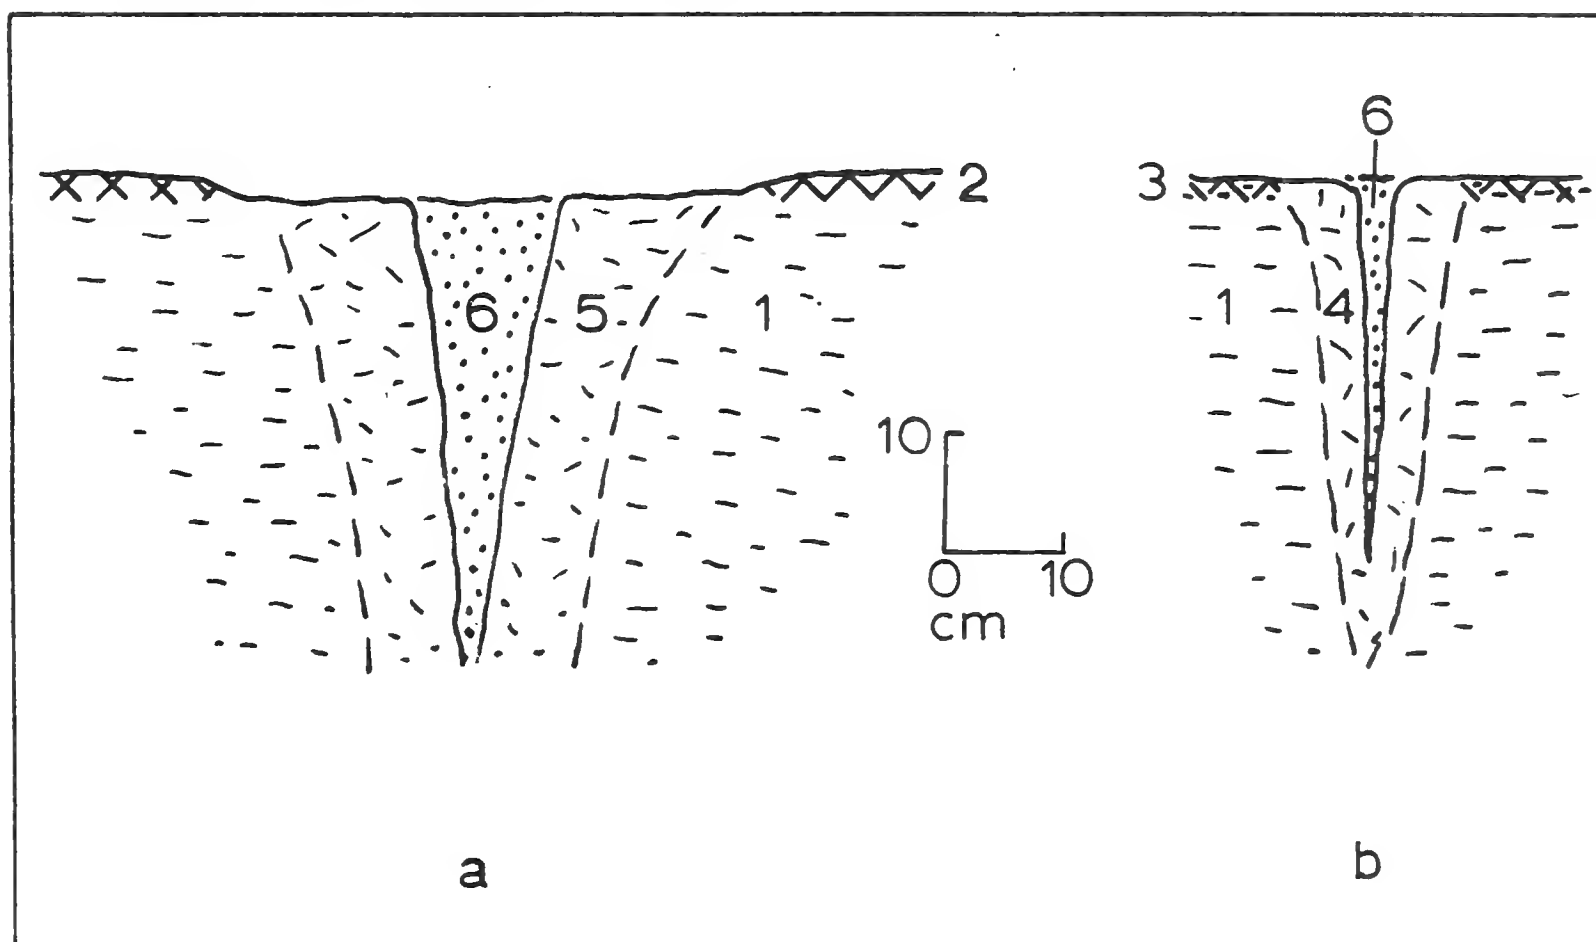

Fig. 2   Sketches of sections across an ice-wedge cast (1961): (a) at foot of cliff; (b) 5 m east of foot of cliff. 1. grey-glue clay of Rootlet Bed; 2. organic mud; 3. muddy clay; 4. yellow-brown oxidised clay, sharp transition to 1; 5. crumbly, weathered yellow clay, merging gradually into 1; 6. coarse ferruginous sand.

K. Gardner and R.G. West
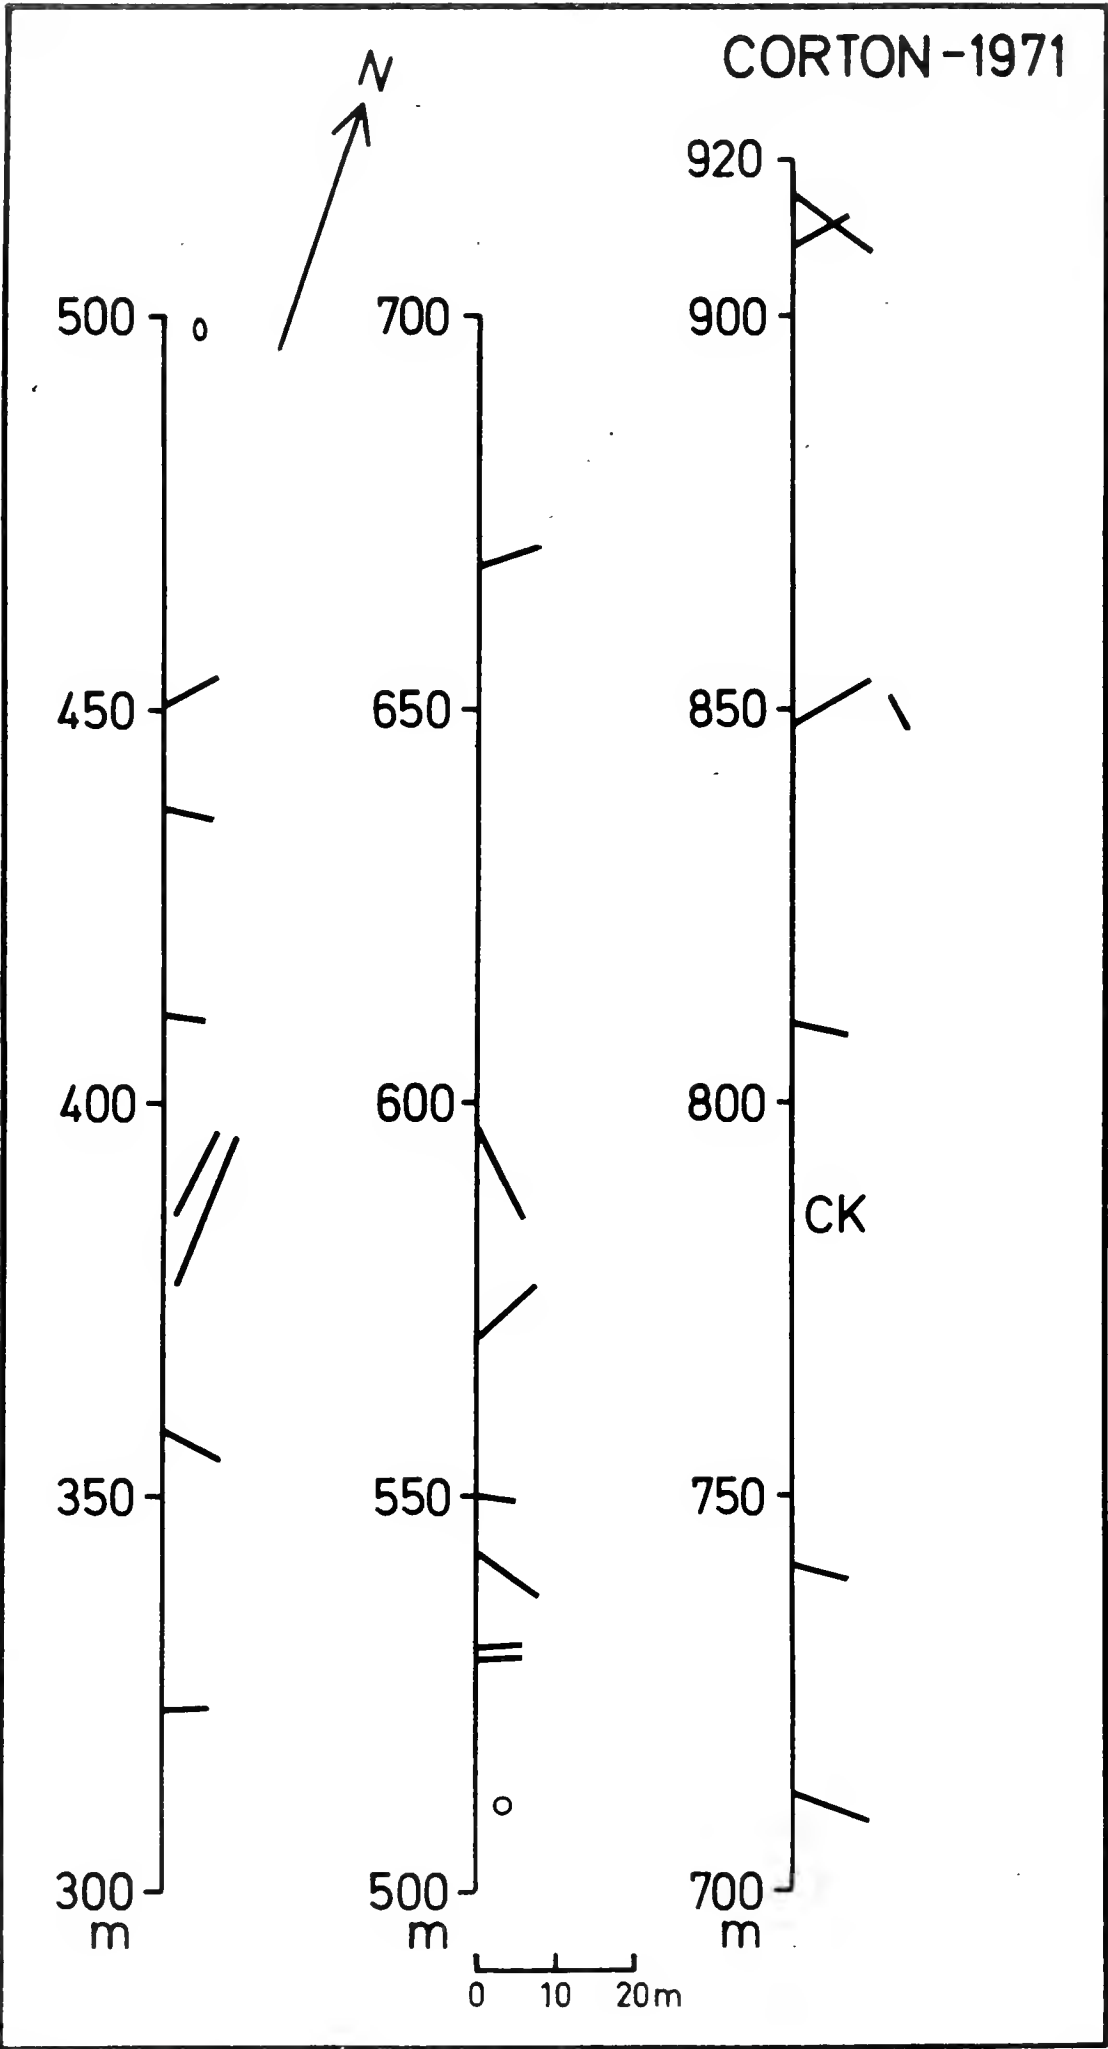

Fig. 3. Plan of ice-wedge casts. Distances in metres N of stair down cliffs opposite St. Bartholomew's Church. CK indicates positions of section under palaeo-botanical study.

Fig. 4   View to seawards of ice-wedge cast penetrating
         peat and Rootlet Bed.

Being an unconsolidated clay, the Rootlet Bed shows
no regular system of jointing, but only small, starch-
like fracture cracks an inch or so apart. There is no
trace of ferruginous weathering along these minor cracks
or over the upper surface of the clay generally. Oxidation
similar to that along the wedges does, however, occur
around the two small basins.

An examination of Blake's (1884) horizontal section
shows that he drew structures interpretable as ice-wedge
casts at exactly the same position along the cliffs as
those seen in 1971, although he did not interpret them as
such. On the horizontal section, the wedges are below
the boulder clay and they penetrate the total thickness
of the tidal sediments, the peat and the Rootlet Bed. In
1971 the upper part of the wedges could not be seen, but
they were observed to penetrate the tidal silts, the
peat and the Rootlet Bed. The polygons evidently formed
subsequent to the Cromerian, during the Anglian cold
stage but before the deposition of the boulder clay.
They probably belong to the same permafrost episode that
produced wedges immediately below the North Sea Drift at
West Runton and at Mundesley. They cannot be correlated
with the ice-wedge polygon system observed immediately
above the Pastonian tidal silts at West Runton (West 1968).

The extent and spacing of the ice wedge casts shows
that a true large-scale arctic polygon system developed
in early Anglian times, before the arrival of Anglian
ice, indicating very low mean temperatures (below $-6^{\circ}C$)
at the time. The 1971 observations also testify to the
powers of observations of J.H. Blake, even though his
correlations of the pre-glacial Pleistocene of the coastal
area were challenged by Reid and Whitaker(in Blake 1890).

THE CONTORTED DRIFT OF NORTH NORFOLK.

P.H. BANHAM*

Introduction

This is a brief account of a lecture delivered to the Society on 18 November 1974. Fuller accounts of the evidence and ideas touched on here will be available shortly (Banham 1975, and in a revised version of "The Geology of Norfolk").

The Contorted Drift is best developed and exposed in coastal cliffs between Mundesley and Weybourne. The complex fold and thrust-raft structures found there in the glacial and glacifluvial deposits have been generally attributed to deformation by ice (Reid 1882, Slater 1926, Dhonau & Dhonau 1963, Banham 1968). This being so, it may be helpful to review the nature of glacitectonic structures elsewhere before considering the Contorted Drift of Norfolk.

Glacitectonic structures in Europe and North America

Four main types of geomorphological site of glacitectonic deformation may be recognized, although it is accepted that these are essentially points in a spectrum.

1.   Veluwe Type (valley sides) In the Veluwe district of Holland superficial thrusts are developed in soft sediments where these had previously been cut by generally northward flowing rivers. These structures have been attributed to valley-side deformation by Saale ice as it penetrated south up the valleys (De Jong 1967).

2.   Møns Klint Type (islands and peninsulas) The Danish islands and peninsulas in the Baltic Sea show many magnificent thrust and fold structures developed in chalk and in the overlying Tertiary and glacial sediments.

*Department of Geology, Bedford College, University of London, Regent's Park, LONDON N.W.1.

Deformation by Weichsel ice during its constricted exit from the Baltic Sea has been postulated (see Hansen 1965).

3.   <u>Missourri Coteau Type</u> (scarps) A large, NW-facing scarp in Saskatchewan and Alberta is the site of numerous thrust-out folds overturned to SE and developed in soft Cretaceous sediments. It has been concluded that ice known to have moved from the NW has deformed the scarp (Kupsch 1962).

4.   <u>The Elkton Rift Type</u> In Ohio a till-filled rift is developed on an interfluve, parallel to the nearby valley. A raft of Coal Measure rocks has been displaced laterally toward the valley to create the rift. It has been argued that in this case ice moved <u>away</u> from the valley side (Lessig & Rice 1962).

Formation of Glacitectonic Structures

    In both the compressional (1-3) and tensional (4) types the following factors in some combination seem to be important in the development of glacitectonic structures:-

(a)   a topographic slope (see Charlesworth 1957, Moran,1971),

(b)   pore water pressure in sediments,

(c)   ice generally at melting point at base (except marginally),

(d)   water drainage towards ice-margin from both ice and land,

(e)   shallow layer of frozen ground, possibly (Mathews and McKay 1960).

Contorted Drift of Norfolk

    Much evidence from mapping, petrological and mineralogical studies now supports the conclusion that the Contorted Drift lithologically consists entirely of the three Cromer Tills, together with the interbedded Intermediate Beds and Mundesley Sands and the overlying Gimingham Sands and Brick Kiln Dale/Briton's Lane Gravels

(Banham 1968). In general, deformation of this sequence
increases from SE to NW.

1.   _Major Folds_   Around Mundesley, broad open basins
and domes affect only the upper part of the sequence -
Third Cromer Till and Gimingham Sands. Further north,
around Overstrand, these domes and basins involve all
beds with the exception of the First Cromer Till and
Intermediate Beds in places. The sinking of the large
basins has been accommodated by the lateral and upward
movement of the underlying beds into the adjacent domes.
Symmetrically developed, overturned isoclinal folds reflect
this movement and are especially well developed in the
Second Cromer Till and Mundesley Sands.

     Even further north and west, between Cromer and
Weybourne, the entire Cromer Tills, etc. sequence, plus
portions of the Cromer Forest Bed Series below, has been
deformed during similar, but more intense, folding con-
sequent on outflow of materials from under basins and
upflow into domes.

     These structures, which have no regional preferred
orientation, and which were initiated at the Third Cromer
Till/Gimingham Sands (clay/sand) interface are regarded
as diapiric.

2.   _Chalk Rafts_   These are perhaps the best known feature
of the Norfolk coast sections. They are most often viewed
between Cromer and Sheringham where their highly variable
attitudes (some are even overturned) are due to the dome
and basin folds already described. Further SE, where
later folding has been less intense (i.e. at Sidestrand
and Trimingham) the thrust masses strike generally E-ESE
and dip N-NNE. As the lowest, First Cromer Till, on
independent evidence, is known to have moved from the NNE
it is concluded that the chalk rafts were emplaced during
the advance of the First Cromer ice. Moreover, Peake and
Hancock (1961) have shown on palaeontological evidence
that rafts have moved approximately along the strike of

fossil zones in the underlying solid chalk (i.e. approx-
imately N-S).

Discussion

The chalk rafts and certain associated minor folds
appear to have been formed during "classical" glaci-
tectonic deformation. The low-angled slope into the
North Sea basin suggests a reduced version of the Missouri
Coteau (scarp) type of site.

On the other hand, the later major dome and basin
and associated isoclinal (etc.) folds appear to have
been formed by diapiric flow of the clay-rich Cromer Tills.
The Gimingham Sands and Britons Lane Gravels reach a
maximum thickness of 60m. (approximately) around Cromer,
and are thought to have provided the load which initiated
these diapiric movements. Geotechnical studies by Kazi
and Knill (1969) have shown that in comparison with
standards at Happisburgh, lithologies in the Contorted
Drift near Cromer are doubly overcompressed.

Structures of similar style and/or size are known
from the Mississippi Delta ("mudlumps"; Morgan et al.
1968) and from a great variety of geological environments
(see O'Brien 1968).

Conclusions

Suggested sequence of events in North Norfolk:
1.   Advances (3) of Cromer Ice from North Sea basin;
      emplacement of rafts during the first advance.
2.   Deposition of Gimingham Sands and Briton's Lane
      Gravels (outwash from Lowestoft ice in large part?).
3.   Diapiric flow of Cromer Tills, etc. under the weight
      of overlying sands and gravels to form domes and
      basins and associated folds.
4.   Truncation of these structures by the present
      topography seems to imply considerable post-Britons
      Lane Gravels erosional dissection, especially near
      the coast.

THE TWO-TILL PROBLEM IN WEST NORFOLK
(a summary of the Presidential Address for 1974,
 delivered 13 January 1975)

H. EVANS*

Two superposed tills have been exposed at Bawsey,
Hillington, North Runcton and in the Nar Valley. The
last three sites were only temporarily exposed and the
Bawsey site is therefore regarded as the 'type' locality.
In each case the junction between the tills is sharp,
and no evidence for an erosion surface or palaeosol has
been recorded.

The till succession for the area has been outlined
in Fig. 1, with each till assigned to a lithologic or
colour characteristic. This has been done to avoid a
stratigraphical bias that might be implied by familiar
stage names.

The Lower Till

This is defined by the interdigitation of Blue Till
with a Ferruginous Till and outwash sands and gravels.
This type of succession has only been found within the
Bawsey area, where it caps the higher ground. Borehole
data, supplied by British Industrial Sands, show a blue
chalky till capping up to 4.50 metres of mixed ferruginous
sands and gravels with discontinuous beds of red-brown
clay. The basal contacts are with Sandringham Sands,
and only one site has been found where a Blue Till caps
Carstone. The outwash phase is mainly found within
subglacial channels, where sub-angular boulders of chalk,
flint and carstone are contained within a matrix of
poorly sorted coarse sands. Laterally the outwash can be
well-bedded and sorted. At two sites ferruginous sands
with thin silts alternate with poorly sorted chalk pebbles

and rock flour, the latter unfilling the matrices. The
succession passes up to basal lodgement till and in total
shows the passage from pro-glacial lake deposition to glacial
advance. The pebbly beds in particular show small scale
shearing and thrusting with a northerly orientation.

The interdigitation of both tills is particularly
well seen where the Blue Till lies in sharp planar contact
with outwash sands. The till contains pods and laminae
of Sandringham Sands indicative of flow tills (Boulton
1968, Hartshorn 1958) where sub-aerial washing has
dissected small channels, which later become infilled.
One site shows a ferruginous flow till capping the washed
surface of Blue Till. In this case the small channel
features have been step-faulted subsequent to melt-out
of stagnant ice blocks.

The lithology of the Ferruginous Till shows a
dominance of Neocomian erratics of local derivation.
The presence of Juassic material is particularly
interesting in terms of the interdigitation of tills, and
contains a suite of typical fossils and rock-types. the lith-
ology of the Blue Till does not differ significantly from the
comprehensive list compiled by Baden-Powell (1948) and
contains a high percentage of Jurassic material. The
erratics are highly angular within the basal till section.
Kimmeridgian shales retain their fissile nature and can
form either irregularly displaced slabs, or imbrication
with strong up-glacier dip. Chalk clasts are faceted
and gouged with percussion marks typical of subglacial
transportation. At North Runcton large doggers are often
striated and gouged. Examination of material within the -1 $\emptyset$
to 1 $\emptyset$ grade showed that up to 50% of total sands
consisted of derived Sandringham Sands.

The roundness of chalk clasts increases up the
succession from 0.35 basally to 0.48 (Roundness Index,
Krumbein 1941) at 2.0 metres. It was found that there
was no significant difference in roundness across the
boundary of superposed tills.

At both Bawsey and North Runcton basal sections showed evidence for up-shearing of bedrock, and in one instance the bedrock sands had been folded. Reference has already been made to the shearing of outwash material. Similar northerly directional trends were found at North Runcton though it is realised that these will vary considerably with the changes of the subglacial terrian.

The Blue Till lithology indicated a flowpath for glacial advance from between west and north-west across the Wash and North Sea (see Fig. 3a), while the angularity of erratics shows a short distance of transport from the source area. The lowest 1.50 metres of the till are indicative of subglacial lodgement till, particularly where shearing is operative. Above this the lack of textures makes classification difficult.

The Calcareous Till

This till lies in planar and sharp contact with the lower Blue Till over much of the area exposed. The exception to this is at Bawsey where compressive forces have up-sheared segments of the lower till. The colour range of this till is white - creamy white, weathering to a light brown at the surface. At the top of the succession the till shows variable soil horizons from site to site which range from rendzinas to podsols. The till matrix is of a chalky-sandy nature but can consist of nearly pure chalk where boulders have been only partially comminuted during transport.

Compared with the lower till there is a great increase in chalk erratics which comprise up to 75% of all erratics. The general absence of both Jurassic and Carstone derivatives is perhaps significant, and suggests that these outcrops were not exposed following the deposition of the lower till.

Textural changes within the Calcareous Till are not readily discernible, and though some chalky gravel spreads are found they do not provide conclusive evidence for interpreting the depositional environment. Only one site

has been an asset in this respect, and this resulted
from the slump of a till face. The fresh surface
contrasted remarkably with the creamy colour described
above.

     The till showed a succession of bedded units with
each unit passing up from subrounded chalk pebbles to
oxidised angular sands and subordinate silts. The sands
contained irregular undulating lenses of <u>Calcareous</u>
<u>Till</u>. Each unit varied in thickness from 0.27 to 0.46
metres, and the total thickness was 2.20 metres. The
pebble phase showed lateral changes in thickness, while
the upper surface was irregular and infilled with the
silty sands. The degree of oxidation increased rapidly
across the junction. The whole sequence was similar to
glacigenic deposits seen in Spitzbergen, where flow tills
form an integral part of gravel-till supraglacial
deposition. Similar sequences in the New England States
have been classified as ablation till (Flint, 1961, Pessl
1968, Drake 1971).

The Contact Zone

     The junction of the superposed till has previously
been described as sharp and planar, though some Bawsey
sections display tectonic features. These are in no way
considered as post-depositional slumping which does exist
in some sections. The junction is generally of very low
relief and shows a slight slope to the WNW.

     Along some sections the contact shows the up-
shearing of bands of lower till which dip downslope at
less than 15 degrees. At such a contact the till under-
lying the shear bands becomes overconsolidated and there
is evidence for crushing within them. In contrast, flames
or fingers of lower till overturn in the upslope direction.
The latter appear to be consistent with ice advance across
a wet till surface.

     The most significant structural features are large
rafts of lower till which can lie up to 1.50 metres above
the junction of the tills. The largest raft was about

3.0 metres in length and 0.80 metres in thickness. The
margins of the rafts showed well aligned and reorientated
clasts, in contrast to the interior, which was unaffected.
The upper surface of one raft showed both shear and drag
folds subparallel to the upper raft surface. These rafts
had only been subjected to short distance transportation
which was evident from irregular trains of <u>Blue</u> <u>Till</u>
dipping down towards the junction.

The observations support the theory that the upper
till (<u>Calcareous</u>) has advanced across the lower, with
rafting occurring in zones of compression within the
glacier ice. This may have been due to advance upslope.
The directional significance of these structures indicates
advance of the till from a direction between NNW to WNW
(see Fig. 3b).

Close examination along the junction of the tills
and the rafted material gave no indication of a palaeosol
or outwash material.

Mechanical Analysis

Samples analysed from the lower till (Blue) for both
Bawsey and North Runcton show a mean modal range from 1.6∅
to 2.6∅(medium to fine sand) and a mean of 2.3∅(fine sand).
The cumulative percentage curves (Fig. 2a) show good
grouping and all are strongly fine skewed. This till is
characterised by a high sand content relative to fines,
with the mean for all samples being 86.8% sand, 7.63%
silt and 5.48% clay. Basal tills tend to show a greater
percentage increase in the sand grade.

The consistent deficiency within the clay-silt grade
suggests that this till may have been well washed of fines,
and that its origin is that of a flow-till. Previous
authors(Holmes 1941, Gravenor 1952) have shown that glacial
advance across shales quickly produces a high clay till.

In contrast, Hoppe (1963) considered clay-poor till
as subglacial lodgement on the evidence of immaturity of
comminution and angularity of debris. The sand grade of
West Norfolk tills show a diminution in shale debris,
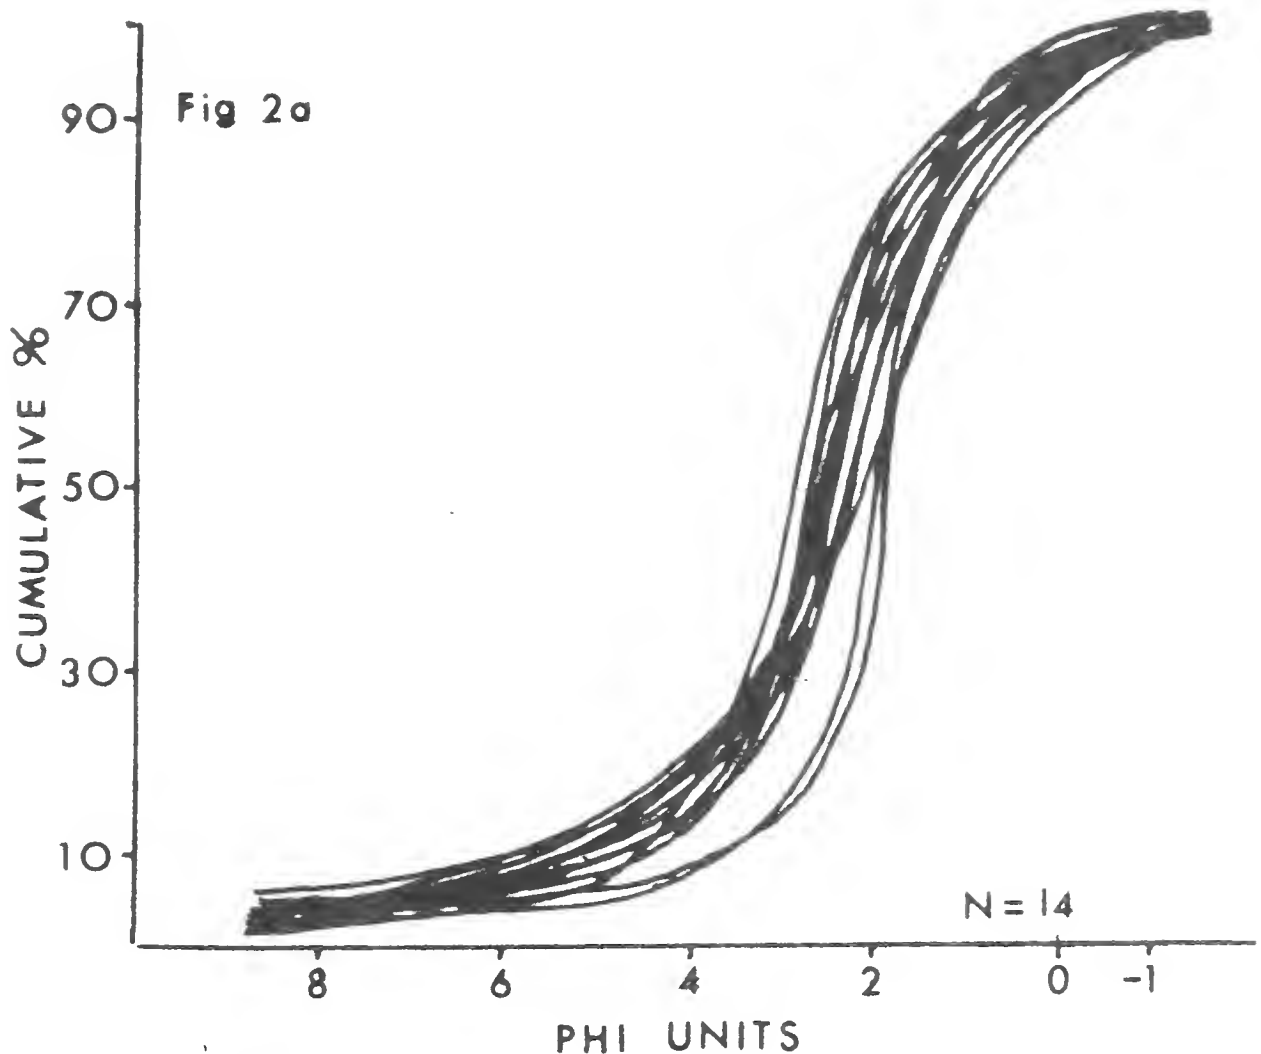

Fig. 2a   Cumulative percentage curves for the lower (Blue)
          till.

within the sand grade, up the succession, so that
comminution has not been as effective as one might
imagine. Certainly the lower 1.50 metres of the lower
till is considered to be subglacial lodgement based on
structures and coarseness of debris.

    In contrast the Calcareous Till shows an increasing
percentage of both silt and clay, while the sand content
decreases significantly. The mean modal range for all
samples is from 3.6∅(very fine sand) to 6.0∅(medium silt)
with an overall mean of 4.42∅(coarse silt). The cumulative
percentage curves (Fig. 2b) are mainly bimodal, the
exception being three finely skewed samples taken from
thrust areas. The mean for all samples is 54.5% sand,
32.9% clay and 12.3% clay.
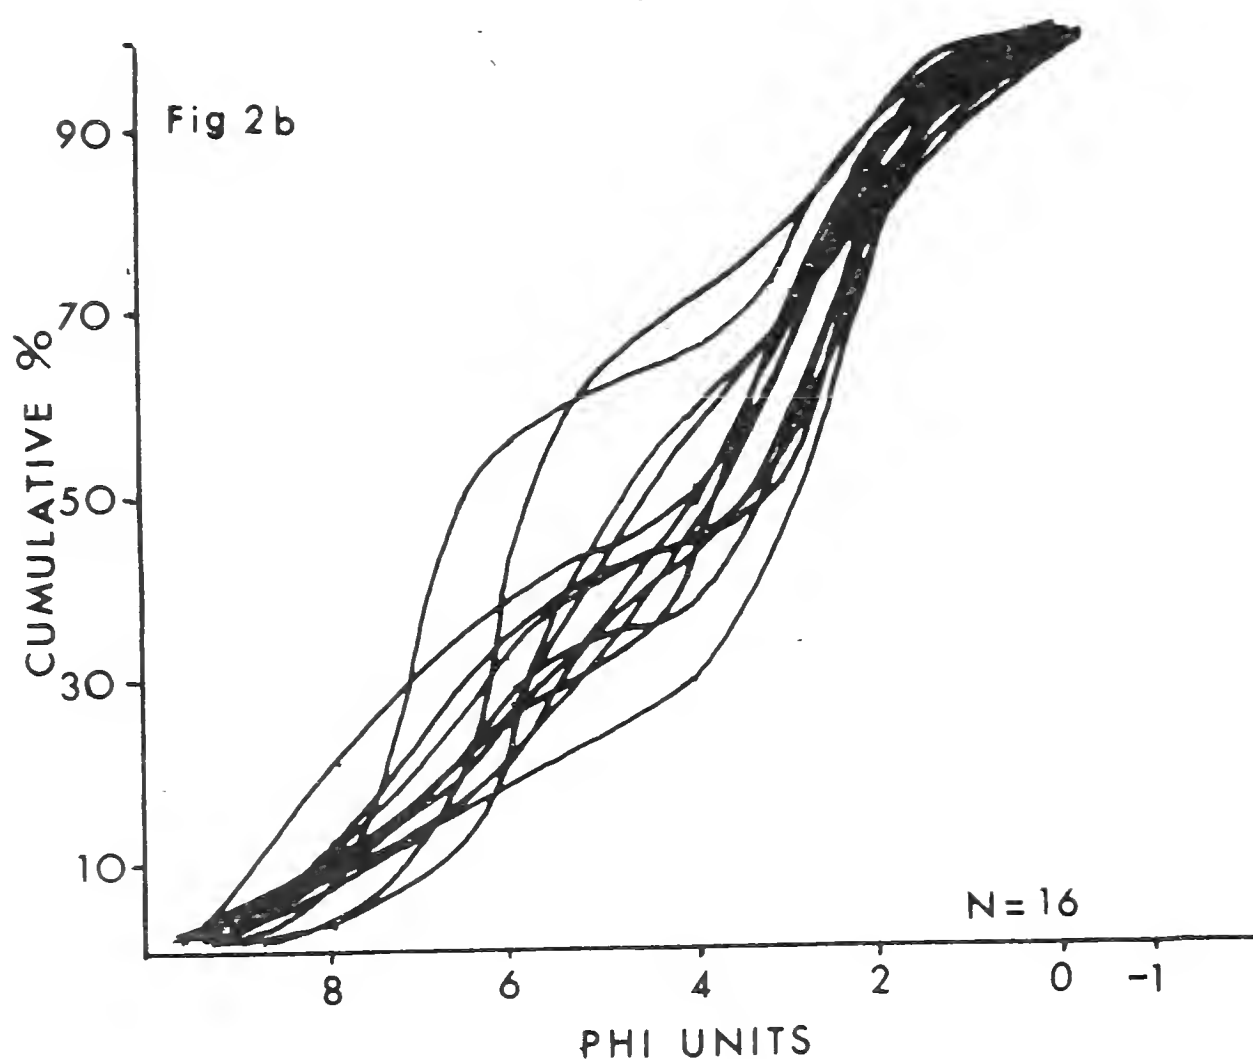

Fig. 2b   Cumulative percentage curves for the upper
          (Calcareous) till.

The textural features of this till are perhaps
more helpful in defining the depositional environment
than the analyses.   Many authors have used a wide range
of silt-clay percent to define 'ablation' tills. Dreimanis
and Vagners (1970) show that comminuted calcareous rocks
are likely to produce a high silt content. My own view
is that textural considerations demonstrate that this till
is of flow origin in part, that is in those sites lacking
compressive textures.

Fabric Studies

Orientation studies were taken at sites where a
relatively complete section was exposed. This enabled
me to make comparative fabric studies between both tills

in terms of vertical and lateral variation. Significant
maxima for each sample have been analysed individually
using Fisher's (1953) function for probability density on
a sphere(Steinmetz 1962), which gives orientation of a
resultant vector $\bar{A}$, its magnitude, a radius circle of
confidence (Θ), and a precision parameter (K). The results
show that (K) values are less than 3.0 while (Θ) values
show a wide dispersion about the vector. Samples do not
show spherical normal distributions.

 When plotted on a Schmitt equal-area projection of
the lower hemisphere all samples are distributed close to
the primitive. Mean dips for samples are less than 15
degrees. The strength of secondary maxima increases up the
succession for both tills.

 A summary of results follows in which comparison is
made with structural data from the tills; Fig. 3a/b
illustrates the results of analyses.

a. Five samples taken from subglacial sections of the
  lower till. Two samples from North Runcton, and one
  from Bawsey, showed orientations between west and
  north-west, the others were transverse to this
  direction. Structures at both localities showed
  orientation between north and north-west.

b. Samples taken at depths between 0.30 to 1.00 metres
  below the junction showed that only two, for North
  Runcton, had a north-west orientation. All other
  samples were transverse to this direction.

c. Above the junction six samples taken within the
  Calcareous Till, showed a consistent north-east to
  south-west trend, and only one sample at Bawsey
  had a north-south orientation. The preferred orient-
  ation of rafted material within this till was found
  to be west-north-west to north-north-west which is
  regarded as the significant orientation for ice
  advance. This trend appears to be fairly consistent
  with measurements for Gipping Till made by West and
 Donner (1956) for sites 1, 9 and 10.

Fig. 3a MAP SHOWING THE DIRECTION OF PREFERRED
ORIENTATION FOR BOTH TILLS. SITE LOCALITIES ARE
I. RISING LODGE, 2. BAWSEY, 3. NORTH RUNCTON, 4. NAR VALLEY.

Fig. 3 b MAP SHOWING THE STRIKE OF MAJOR STRUCTURES
WITHIN THE SUBGLACIAL BLUE TILL (—▲—), AND CALCAREOUS
TILL (–▲–) WITH RAFTED INCLUSIONS.

Vertical sections taken across the junction show that
the north-east to south west orientation is common to
both tills, and may suggest reorientation of the lower
till (MacClintock and Dreimanis 1964, Penny and Catt 1967).

Conclusions

1.   That the lower till (<u>Blue</u>) advanced from a north-
       westerly direction - based on structural elements,
       fabric studies and lithology. This stage of ice
       advance shows interdigitation with a ferruginous
       till and outwash which is only evident within the
       Bawsey area. Both tills contain a high percentage
       of angular erratics and these are mainly of local
       derivation with a short distance of transport from
       their source areas. Bawsey is only some 6 kilometres
       from the Jurassic outcrops. The lower part of the
       <u>Blue</u> <u>Till</u> is definitely subglacial lodgement though
       the lack of change in comminution up the succession
       suggests that it could be lodgement throughout.

2.   The upper till (<u>Calcareous</u>) shows lateral variation
       of textures between contrasting zones of compression
       with those of extensive flow. The former is exempli-
       fied by shearing and rafting across an otherwise sharp
       planar contact, while the latter consists of flow till
       in part. The compression may well have been due to
       advance uphill from the Wash. The presence of rafts
       shows that this till advanced across the lower till
       from a direction close to that observed for the lower
       till.

3.   The lack of palaeosol or outwash at the junction
       suggests that insufficient time elapsed for either
       an interstadial or interglacial period.

The most likely explanation of the two-till problem is
that the upper till is a readvance phase across a stag-
nating lower till, and that both tills are of the same
glacial stage. Brickearths with scattered <u>Cardium</u>, <u>Ostrea</u>
and <u>Buccinum</u> are found to overlap a till succession 500
metres to the north of the Bawsey Site. Rose mapped these

         Blue and Calcareous Tills.

Fig. 5. Large raft of Blue Till within the Calcareous Till; the upper surface of the raft has been sheared with a prominent nose to the right.

deposits as <u>Nar Clay</u> in 1865. Confirmation for the age
of these beds has not been fully established, but I
tentatively suggest that the tills may well be <u>Anglian</u> in
age.

SECRETARY'S REPORT FOR 1974

The normal venue for meetings at the University of East Anglia seems to have established itself fairly well, thr ugh there is sometimes some difficulty experienced by newcomers in finding the relevant lecture room. Throughout 1974 we were obliged to use no less than four different rooms in the University. With the opening of the Library extension it is hoped that the use of the Library Conference room will become the room.

During the year the following lectures took place: January: Dr. P.N. Chroston on "Geophysical Investigations of the Palaeozoic Floor of Norfolk", followed by a demonstration of geophysical equipment. February: Professor J.C. Cummings on "The San Andreas fault and Californian Geology". March: Dr. G.S. Boulton, at a few hours notice, gave a talk on "Aspects of glacial deposits, Recent and Quaternary", for which we are all very grateful as Dr. Banham, who was scheduled to lecture, was unfortuaately prevented from doing so by an attack of 'flu. November: Dr. P. Banham on "Aspects of contorted drift". December: The A.G.M. was followed by showing of members' slides and demonstration of speciments.

The standard of lectures throughout the year has been consistently high and on behalf of the Society I would like to thank the lecturers who have provided a stimulating programme.

February 1975.   Christopher J. Aslin.

BULLETIN OF THE
GEOLOGICAL SOCIETY OF NORFOLK

No. 28

1976

CONTENTS INCLUDE:

EDITORIAL

       Our policy of having a double or annual edition of the Bulletin

is continuing this year as part of our policy to keep prices low. We

must be the society with the lowest subscription charge in Norwich by

now, which has both publications and meetings included in that very low

annual charge. Not a little of this is due to facilities provided

by the University of East Anglia, and the careful housekeeping of our

Treasurer. Our thanks are also due to Norman Peake, who has organised

many field trips over the last few years, but is now stepping down. His

deep knowledge of the Chalk has been at our service unstintingly and we

have learned much from him.

       The Presidential Address this year was stimulatingly, not to say

provocatively, delivered by Professor Keith Clayton, who is already

well-known to us all. His theme of coastal erosion drew engineers

into the discussion which followed, providing us with other views on a

subject of continuing interest for all, and continuing worry for some.

Our other contributions this time include a paper from W.M. Corbett

and C.A.H. Hodge of the Soil Survey on the Drift deposits behind

Sheringham, and a further contribution of interest to engineers from

P.F. Wilkes, of the County Highways Department, on highway engineering.

       Bulletin 29 will be issued in April 1977. Contributions should

be sent to me as soon as possible, and certainly no later than 31

October 1976.

Will contributors please note that manuscripts are acceptable in legible handwriting, although typewritten copy is preferred. In either case it would be a great help if details of capitalisation, underlining, punctuation, etc., in the headings and references (particularly) could conform strictly to those used in the Bulletin.

Illustrations intended for reproduction without redrawing should be executed in thin, black ink line. Thick lines, close stipple, or patches of black are not acceptable, as these tend to spread in the printing process employed. Original illustrations should, before reproduction, fit into an area of 225 mm by 175 mm; full use should be made of the second (horizontal) dimension,which corresponds to the width of print on the page, but the first (vertical) dimension is an upper limit only. All measurements in metric units, please

R.S.J.

DISTRIBUTION AND LITHOLOGY OF DRIFT BEHIND SHERINGHAM, NORFOLK

W.M. CORBETT and C.A.H. HODGE*

Introduction

"After spending about a year in Norfolk I began to believe I knew all about the Drift, but during the following seven years of my sojourn in that county, as I moved from place to place, I somehow seemed to know less and less; and I cannot say what would have been the result, but fortunately the Geological Survey of the county came to an end." (Woodward 1885)

The soils of Ordnance Survey sheets TG 13 (Barningham) and TG 14 (Sheringham) covering much of the Cromer ridge, were mapped by the Soil Survey of England and Wales during 1968-69.

Geological sources for the western half of the Barningham/ Sheringham sheet are the Geological Survey Old Series Sheets 68 N.W. and 68 S.W. and the accompanying memoir (Woodward 1884) and for the eastern half Old Series Sheet 68 E. and its memoir (Reid 1882). The mapping of the area now covered by Ordnance Survey Sheets TG 13/14 was split between these two officers, Reid covering the northern two-thirds between 1876-80, and Woodward the southern one-third during 1876-83. The complexity of the district forced them to compile essentially lithological maps (Table 1). The mapping was shared but there is divergence in the lithological keys, blue being used for Calcareous masses or Marl on Sheet 68 E, for Marly Clay and Loam (Contorted Drift etc) on 68 N.W., and for Boulder Clay (i.e. Chalky Boulder Clay) and Marl on 68 S.W. Other workers who have written about land within TG 13/14, mostly with reference to the

* Soil Survey of England and Wales, Government Buildings, Block B, Brooklands Avenue, CAMBRIDGE CB2 2DR

4   W.M. Corbett and C.A.H. Hodge

coastal cliff sections, are Boswell (1916), Solomon (1932), Banham

(1965, 1968), Banham and Ranson (1965) and Ranson (1968). West

(1957), Sparks and West (1964) and Straw (1965) have considered the

geology in relation to landforms mainly for the district around Holt

immediately west of TG 13/14.

Data on soils within TG 13/14 were obtained by augering with an

inch diameter 3 ft. (1 metre) screw auger at an intensity of 30-55

bores per square kilometre. Analyses, including calcium carbonate

content and particle size distribution were made by the Soil Survey's

analytical section, using samples from specially dug soil profile

pits. Some samples were also taken from deeper cores and from

exposures in disused pits, for analysis of calcium carbonate con-

tent and particle size distribution by Dr. R.M.S. Perrin and his

staff at the School of Applied Biology, University of Cambridge.

Particle size analyses by the Soil Survey are plotted on triangular

co-ordinate diagrams and those by Dr. Perrin, with smaller grade

intervals, as cumulative curves.

Three soil parent materials have been identified; a brown drift,

a marly drift, and a cover loam, and their distribution is shown in

Figs. 1, 2, 3 and 4. Their distribution and lithology as established

by soil survey is of interest especially as the area is important in

the East Anglian Pleistocene stratigraphic succession (Bristow and

Cox 1973).

The Brown Drift

This is within auger depth over much of the south-east quadrant

of TG 13/14 at heights between 75 ft (23 m) and 175 ft (53 m) O.D.

and on higher ground between 200 ft (61 m) and 250 ft (76 m) O.D.

between Hempstead and West Beckham; the Glaven catchment on the
Cromer Ridge (Figure 1). On the coastal plain it is on either side
of Sheringham between the sea-cliffs and the 175 ft (53 m) contour
marking the north face of the Cromer Ridge on the adjacent Kelling
Heath (Holt) outwash plain to the west. This area has Brown Drift
within auger depth or, on the evidence of gley morphology of the
superficial sand, near the surface.

The material is a brown* unsorted slightly mottled firm sandy
loam or sandy clay loam (Table 2, Fig. 5a). It can be seen in a
road cutting near Calthorpe (TG 181311). Cox and Nickless (1972)
describe Norwich Brickearth near Norwich as structureless till of
brown sandy clay, and Boswell (1914, 1916) gives a very similar
description, noting that it has field characteristics quite distinct
from other deposits and a constant particle-size distribution over
an area of 350. sq. miles north and east of Norwich. These descrip-
tions match those of the Soil Survey and, allowing for differences
in technique, Boswell's particle-size distribution, for samples from
one site at Cawston about 3 miles to the south of TG 13/14, are also
similar. The Brown Drift found in the south-east quadrant of the
map is thus regarded as a north western part of the Norwich Brick-
earth outcrop. The area of Brown Drift in the south-east of TG 13/14
is broken up in Fig. 1 because of numerous valley floors with super-
ficial deposits which separate the outcrops of the drift.

Figure 1. Brown Drift (Norwich Brickearth, Contorted Drift) behind Sheringham.

Brown drift on the Cromer Ridge on the south side of the Glaven valley between Hempstead and West Beckham and on the Coastal Plain is lithologically similar to the material in the south-east quadrant of TG 13/14 (Table 2). On the coastal plain it was identified in auger borings as far west as Weybourne.

The distribution of the "Loam and Clay with nests of sand,etc." of the Contorted Drift in the Old Series geological map 68 E. is broadly similar to that of the Brown Drift in Fig. 1, but on 68 N.W. no distinction was apparently made between Loam and Marl which are grouped,and no separate outcrops are shown between Sheringham and Weybourne. On map 68 S.W.,where Loam was distinguished,the outcrop in the Glaven valley is displaced to the south east in relation to the Brown Drift shown in Fig. 1.

Well records held by the Institute of Geological Sciences show the core of the Ridge in the western and central part of TG 13/14 is clay, thinner sand and gravel separating this from a level chalk surface beneath. This suggests the Brown Drift extends laterally along the Ridge to the Contorted Drift in the coastal cliff, out-cropping within the ridge in the Glaven valley. There are, however, no well records east of Sheringham to confirm this. South of the ridge in the south-west of TG 13 the records show thinner clay under sand and gravel.

The Marly Drift

This is the Marly Drift of Woodward (1884) and Straw (1965), a very pale brown to white, very calcareous firm drift,fairly free of non-chalk stones (Table 2). Calcium carbonate is often 70 and

TABLE 2

80 per cent but values over 90 per cent have been recorded (TG
161399 East Beckham, 95.6 per cent $CaCO_3$). The field appearance
is quite distinct from Brown Drift but the particle-size distribution
of carbonate free material (Table 3, Fig. 5a, 6) is variable; some
samples are similar to the Brown Drift, others have more clay and
silt. Mottling as an indication of impeded drainage seems associated
with more clay in the non-carbonate fraction.

In the mapped area there is no spatial pattern in calcium
carbonate content but samples at Sustead (TG 186377) and West Beckham
on the Cromer Ridge (TG 113339) show decreasing carbonate
and increasing non-carbonate sand with depth (Fig. 6). The lowest
samples from both places have a particle-size distribution similar
to the Brown Drift and carbonate values between Brown Drift and
Marly Drift. Similar material was found in the south-east in Wolterton
Park to the south of other Marly Drift outcrops, well within the
Brown Drift area.

The largest outcrop is on the coastal plain around Weybourne
below the 175 ft (53m) contour which marks the north edge of the
Cromer Ridge (Fig. 2). Elsewhere it is in small isolated outcrops,
on the coastal plain between Weybourne and Sheringham, on the
ridge south of Sheringham and between Hempstead and West Beckham,
and to the south again at about 175 ft (53 m) along the southern
margin of the ridge. There are a few still further south in the
area of Brown Drift.

Most occurrences on the ridge are to the north and south and
are closely associated with Brown Drift. This is true of the

Figure 2. Marly Drift near Sheringham

outcrops on the Ridge and on the coastal plain where brown drift adjoins the main mass of the Marly Drift at Weybourne. The West Beckham (TG 138389) bore passed through Brown Drift into Marly Drift (Table 3). The exceptions to this pattern are occurrences south of Sheringham and in the south-west near Saxthorpe in areas of sand and gravel.

Comparison of the Old Series Geological and Soil Survey maps shows a fairly good agreement on occurrence but very big differences in the extent of the Marly Drift. Geological map 68 E. shows "Calcareous masses or Marl", a subdivision of the Contorted Drift, behind Sheringham around East Beckham and near Felbrigg, the out- crops in each locality covering a considerable area. In the big area of Contorted Drift to the south of the ridge small patches are shown fairly frequently, particularly near the ridge gravels. These are all more extensive than found in soil survey. On 68 N.W. no dis- tinction was made between Marl clay and loam, and no comparison can be made. However on 68 S.W., which covers the greater part of the west side of TG 13/14, Boulder Clay and Marl are mapped together and are shown as widespread in valleys between Saxthorpe and Holt where soil survey showed the Marly Drift to be rare and Chalky Boulder Clay absent.

Reid (1882) ,noting many marl pits between upper Sheringham and Beckham ,commented that the Contorted Drift was more marly to the west. It seems probable that estimation of the extent of Marly Drift from the examination of marl pits alone, might give an exag- gerated impression of its extent. In an area of acid sandy soils marl pits would be of great importance and every outcrop exploited,

*Texture classes are of carbonate free material

whilst the presence of Cover Loam as a thin superficial deposit
in the valleys would tend to obscure the true extent.

Sands and gravels cover most of the rest of the map. On the
North side of the Cromer Ridge these are stony and do not contain
Marly Drift. South of the watershed between the Bure and the
coastal streams, they are stratified sands, with some Marly Drift
inclusions. The I.G.S. well records show Marly Drift within the
ridge only in the sands and gravels immediately above the clayey
core. The close association of Marly Drift and gravel was noted in
the district west of TG 13/14 by Straw (1965).

The Cover Loam

The Brown Drift in the lowlands in the south-east and the
sands and gravels of the ridge are covered by a thin superficial
deposit (Fig. 3). This is a non-calcareous brown loam, and it is
the most widespread soil parent material in the district. It is
absent from most of the coastal plain.

In profile there is a sharp boundary between it and the under-
lying drift, a sharp textural change at depths between 40 and 200
cms. A typical section at Hole Farm, Hempstead (TG 115353)shows:-

    0- 35 cm, dark yellowish-brown 10YR 4/4 non-calcareous loam,
          slightly stony.

    35- 80 cm, strong brown to brown 7.5YR 5/6-4/4 non-calcareous
          loam, slightly stony.

    80-100+cm, yellowish-brown 10YR 5/8 and yellowish-red 5YR 5/6
          non-calcareous very stony sand.

Locally this material is thicker on the gentle north and east facing
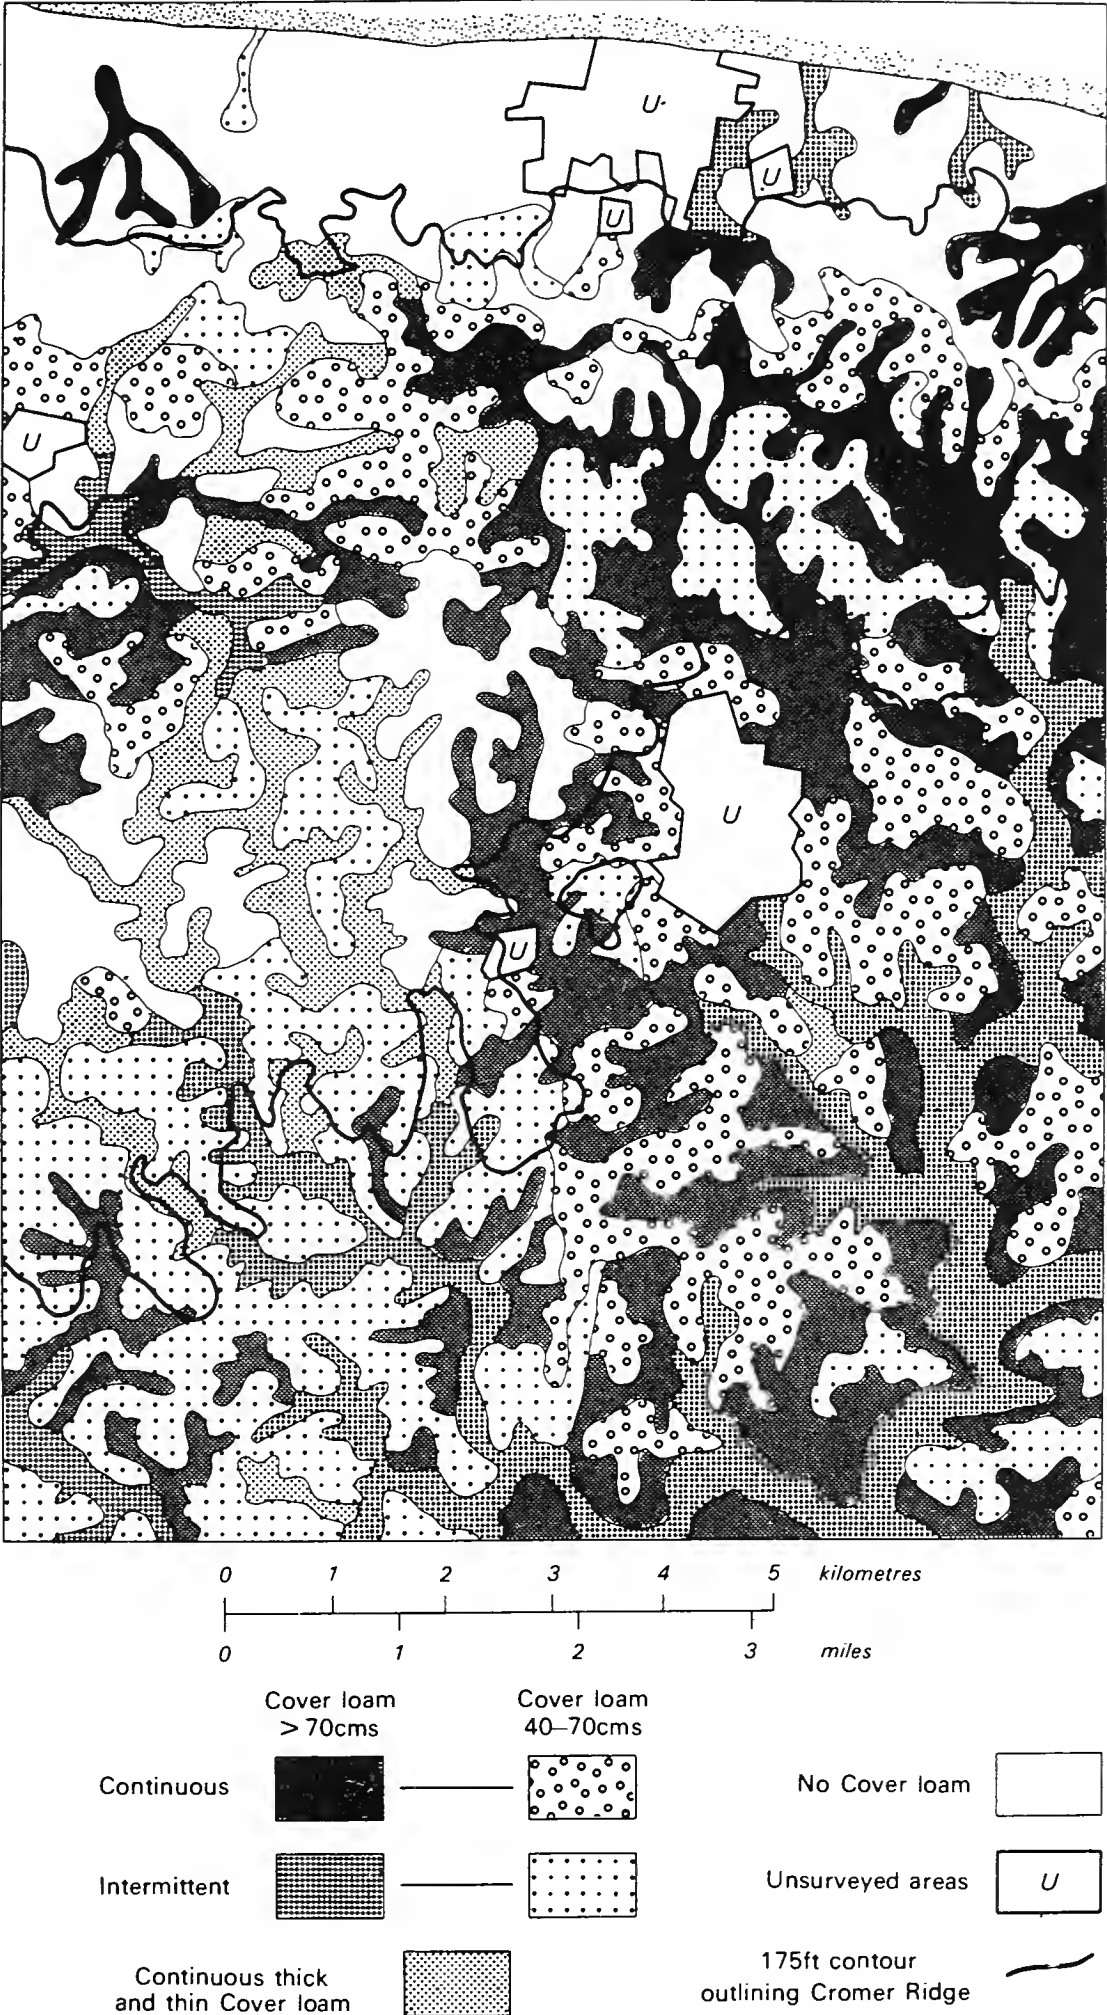

Figure 3. Cover Loam

slopes and thin or absent on the steep slopes facing south and west. It is thickest in valleys, dells in valley sides and in other slight depressions in the landscape. The maximum thickness is about 200 cm. It tends to be absent from small crests and narrow ridges.

The nature of the textural change is shown in Fig. 5b. Cover Loam samples with 20 to 50 per cent silt and 5 to 20 per cent clay are a distinct group from sand and gravel with low silt and clay and Brown Drift (Norwich Brickearth) with more clay. It seems unlikely that post-glacial weathering produced such material from dissimilar substrates. Catt et al.(1971), from particle-size and mineralogy conclude it to be loess with material from below mixed in, and in this area Cover Loam over the Brown Drift tends to have more clay for a given silt content than over sand. Ranson (1968) had previously noted a possible loess deposit on the Cromer Ridge east of sheet TG 13/14. More recently Perrin, Davies and Fysh (1974) have defined the distribution of late Pleistocene aeolian dep- osits in eastern England and TG 13/14 falls into lithological prov- ince IV in which topsoils are enriched in wind-transported silt and sand. Over both sands and Brown Drift the thickness of the Cover Loam increases as the silt content rises and the sand and stones decrease. The exception is the surface plough layer which is almost always slightly sandier than the immediate subsoil. These trends are consistent with Cover Loam being formed by the mixing of loess with the substrata. Periglacial disturbance brought up and mixed tongues of underlying material (Hodgson 1967), and the wind throw of trees and animal burrowings might contribute to this. Particle-

size analysis of loess (Catt et al. 1971),at two places within

TG 13/14,give a single distribution curve when the sample has much

silt,suggesting sorting from a single source, and a characteristic

double curve when there is more sand, indicating a composite material

(Fig. 6):

Analyses for Cover Loam occurring on contrasting substrata are

available from 29 sites; 20 on sands and 9 on the Brown Drift

(Norwich Brickearth). Regressions were fitted to sites and soil

properties for these profiles using the Rothamsted MLP programme

written for the ICL 4-70 computer. Although the sites were selected

to represent soil profile classes separated partly on depth of Cover

Loam there was a low correlation of thickness with map position

and the sites may thus be regarded as a random selection in space.

As expected from field observations silt content was correlated

with thickness on the 15 sites where the depth of Cover Loam over

sand was measured. The equation z (per cent silt) = -3.97 + 0.62d

(depth cms) accounted for 51 per cent of the variance, the regression

coefficient being significant at the one per cent level. Correlation

of silt content with thickness on the Norwich Brickearth sites was

less good so that over all 29 sites only 20 per cent of the vari-

ance in silt content could be accounted for in terms of depth.

Of the variates fitted, the best correlation was obtained

between silt content, thickness of Cover Loam, and the three figure

Eastings co-ordinate of the Grid Reference of the sites. Using the

data for the 29 sites, 57 per cent of the variance of the silt can

be accounted for by z (silt content) = -13.29 + 0.21e (Eastings)

+ 0.3d (depth cms) the regression coefficients being significant

at the 0.1% level. For the 15 sites with a measured depth to sand,

79% of the variance could be accounted for by z = -27.42 + 0.19e +

0.15d ,again significant at the 0.1% level. The increase in silt

with direction supports the hypothesis that the Cover Loam contains

windblown loess. Assuming silt content of loess increases with

distance from the source, this lies to the west, or more probably

to the north-west as inclusion of the Northing grid co-ordinate as

a variate gives a non-significant negative regression coefficient.

Cover Loam is absent from the highest, most exposed parts of

the Cromer Ridge above the 300 ft (92 m) contour and from the crest

of the steep north face above 200 ft. (Fig. 4). On these surfaces

there is more silt in the plough layer than in the subsoil. On the

steep north face of the Cromer Ridge the absence of silt could be

due to erosion. On high, relatively flat exposed positions it may

never have been deposited. It is present on gently sloping land

nearby,more liable to erosion. Thick deposits on valley floors

often show a more sandy upper part, the product of local movement,

and a lower more silty part representing original deposition.

Windborne deposits, either cover sand or loess, are common in

Europe. Intermediate sand-loess occurs in Belgium and similar

mixed deposits have been described from the Veluwe near Arnhem by

Vink (1949). Valley loess there is partly mixed with sand by soli-

fluction. The landscape is similar to Norfolk and the distribution

pattern likewise lobate with loess extending upslope in re-entrants

and across cols. In both cases the pattern can be correlated

Figure 4. Area without Cover Loam.

imperfectly with relief. Undisturbed loess in Holland has more

silt than the Norfolk Cover Loam but loess mixed with sand has a

similar particle size distribution. On triangular co-ordinates

(Fig. 5b) the particle size distribution of Cover Loam occupies

similar space to samples of cover sand and loess taken throughout

the Netherlands (de Bakker and Schelling 1966, p. 55).

This thin deposit is not recognised in the Old Series geological

maps but on 68 SW the area between Corpusty and Holt mapped as

Boulder Clay and Marl has a somewhat lobate pattern, tends to

delineate low lying ground and in several places is annotated

loamy. It seems probable that the boundaries here are those between

the Sand and Gravel and the Cover Loam which was regarded as soil

covering Marl.

Discussion

The Ridge is conveniently defined on the north and south by the

175 ft. contour. To the north on the coastal plain around Weybourne

is Marly Drift and to the east of this areas of Brown Drift (Con-

torted Drift, North Sea Drift, Norwich Brickearth). On the south

side, the lowlands to east and south east of Matlask are cut in

Brown Drift and to the south and west towards Corpusty this is covered

by thin sands.

Above this height are sands and gravels, to the south of the Bure

watershed laminated sands with few stones and to the north stony

sands. The Glaven cuts down in the centre of the ridge to expose

Brown Drift above the 175 ft. level marking the Ridge boundary in

the north and south. This indicates a Brown Drift core capped by

sand and gravel as postulated from cliff sections at Overstrand.

Marly Drift occurs away from Weybourne only as small isolated
outcrops in the Brown Drift near the Ridge boundary,or in the Ridge
sands near their boundary with the Brown Drift.

These drifts forming the soil parent materials are distinct
and easily recognisable in the field. They form the overall simple
pattern summarized above,although the detailed distribution is
complicated. A soil parent material map thus parallels the simple
arrangement of geological deposits shown at a smaller scale on the
Old Series geological maps of the last century. However, the strati-
graphy is complex,as is well known from the cliff sections between
Weybourne and Happisburgh,and this is obviously also true of the
association of Marly Drift, Brown Drift, and Sands observed in
mapping sheets TG 13 and TG 14.

Thus no stratigraphic correlation is attempted between the
Brown Drift and the 1st, 2nd and 3rd tills (Banham 1968, Ranson
1968) of the Contorted Drift on the coast,or between these and the
Marly Drift,or the latter with the Lowestoft till (chalky boulder
clay),as this needs more specialised work than can be attempted as
an adjunct to a soil survey.

In a wider context Bristow and Cox (1973) have suggested that all
these deposits are"penecontemporaneous" and are part of a single
glaciation. Before this can be established it is likely that
detailed mapping may be needed,especially along the line Fakenham,
Foulsham, Reepham which Woodward (1884) indicated as the lithological
junction zone between the Chalky Boulder Clay and the Marly Drift.

Marly Drift and Cover Loam (carbonate free determinations).

Soil survey is principally for agricultural purposes and in this district the most important superficial deposit forming soil is the Cover Loam. This has previously not been recognised by geologists. It is, however, the principal factor in the fertility of the area. Without this blanket of, as we believe, windborne Devensian silt, most of the land would be either dry infertile sand or intractable clay loam.

Summary

Three lithologically distinct soil parent materials were identified during a soil survey of the 135 km^2 of Ordnance Survey sheets TG 13 and TG 14. A brown drift corresponds to the Norwich Brickearth.and the Contorted Drift, and a marly drift to the Marly Drift of previous workers. A thin superficial cover loam overlies outcrops of both,as well as over sands,and is regarded as being largely of Devensian windblown material. The distribution and nature of these deposits are described and related to previous geological maps.

THE PROBLEMS OF THE HIGHWAY ENGINEER IN NORFOLK

P.F. WILKES*

Introduction

The general highway engineering problems associated with the geology of Norfolk will be discussed first. The second part of the paper consists of a number of case studies of highway schemes that have been completed or are under preparation.

Generally the highway engineer is interested in superficial deposits for the construction of embankments and cuttings. Of concern are the behaviour of the various materials in respect of stability, settlement and the suitability or otherwise of the materials to form component parts of a highway, for example, bulk fill, sub-base, concrete aggregates, etc. Where bridgeworks and other structures are involved the ability of the deposit to take the higher loadings imposed by the foundations is also of considerable interest, although in Norfolk a large number of such structures require piled foundations. In those cases a knowledge of underlying deposits becomes essential.

General problems

An inspection of the Geological Survey Map, Drift Edition, for Norfolk reveals that the deposits of main concern to the highway engineer are almost entirely Quaternary deposits. The geological history of the Quaternary deposits in East Anglia is complex. However it is the alluvial and fen deposits which create the majority of stability and constructional problems, as these are generally highly

* County Highways Dept., Norfolk County Council,

County Hall, Martineau Lane, NORWICH, NR1 2DH.

compressible and of low strength.

In addition to the natural features that the geological succession has provided in Norfolk - flat expanses of Fenland to the east, a generally low lying aspect to the whole county with little rapid change in elevation - artificial features can be seen which affect the deposition of new material, the most prominent of these features being, perhaps, the Broads. At one time these were considered to be naturally occurring; however, recent evidence points to their being the result of peat digging. The more recent artificial features are to be found in the east of the county and in Cambridgeshire, where large scale flood relief and drainage works have been carried out, including diversion of the Great Ouse River into man made "cuts. Gravel and other mineral extraction will also have their effect on the ultimate geological sequence in parts of the area.

Examining the behaviour of the various strata as engineering materials, it is convenient to consider these materials in two broad categories; those suitable for engineering purposes and those unsuitable.

Suitable materials are those on which, or in which, highways and associated structures can be constructed with minimum problems. There are also those which may be used for constructional materials, for example as fills, concrete aggregates and in gravel asphalt. Such suitable materials include sands, gravels, boulder clays, brickearths and the like, which generally present the engineer with few difficulties in their use or re-use. On excavation or subsequent rehandling some of the materials may require careful treatment, for instance brickearths, and to a lesser extent boulder clays, become intractable

materials during inclement weather conditions when the moisture con-
tent increases. (Conditions which invariably pertain when a job
becomes delayed for one reason or another and there is no float re-
maining in the earthworks programme.) Alternatively during long
spells of dry weather compaction problems occur with some of these
materials; a further hazard in these conditions is the formation of
dust clouds which without fail seem to reduce a world record for some
valuable agricultural crop to abysmal failure! Generally however,
the engineer can expect little difficulty in areas where these mat-
erials abound, and these virtually cover Central Norfolk.

Unsuitable materials are the alluvials and fen deposits which
can be found to the west and east of the County, and also along the
courses of the multivarious streams and rivers. These alluvials
and fen deposits are invariably of low strength, highly compressible,
and generally exhibit overconsolidated features, the latter being
usually difficult to quantify at site investigation stage. By their
very history of deposition they are also of a very variable nature.
These materials require the use of various engineering techniques
to allow the construction of highways and bridges on them. The tech-
niques can be manyfold, for example: complete excavation, displace-
ment, stage construction, surcharging and the use of facines. For
the engineer selecting a route for a new road,a consequential prob-
lem occurs in alluvial areas. The alluvial deposits in Norfolk
appear to produce either a habitat suitable for rare flora or condi-
tions which in turn support rare fauna, for example orchids and
micromoths, and therefore a number of S.S.S.I.'s (Sites of Special

Scientific Interest), nature reserves and bird sancturies exist in
Norfolk. A new highway route will often cut through these or affect
the conditions in such a manner that the flora or fauna are in danger
of being destroyed, unless the engineer makes every effort to main-
tain the natural conditions on each side of the works.

A feature of the area, particularly the fenland are the 'islands'
of gravels, boulder clays and the like within the alluvials, on which
settlements have been constructed. Also towns and villages have
usually been developed right to the edge of the more solid materials,
leaving the area bounded by the alluvial deposits. Therefore any
bypass route is forced onto the poor ground.

The investigation of the various strata can give rise to some
concern to the engineer. Each type of material has its own inherent
problems, particularly in obtaining samples. Disturbed samples
present no difficulty. The problems arise in undisturbed sampling,
particularly in the alluvial deposits. It has been found that the more
reliable methods of obtaining parameters of the various materials
are to utilise in situ means wherever possible. Boulder clays are
difficult to sample because of their constitution. However, experience
in their use shows that from an engineering point of view their
behaviour is consistent, there is little long term settlement and
no stability problem. The various alluvials and fen deposits, on
the other hand, require careful handling, as the materials are sus-
ceptible to sample disturbance.

The adage "a site investigation is only as good as the quality
of the sampling" certainly holds true for these materials.

The natural features of Norfolk, i.e. flat expanses of fenland, its generally low lying aspect with little variation in elevation, give rise to yet another problem for the engineer, that of provision of adequate drainage. In some areas the use of soakaway techniques is possible and in some instances deep soakaway boreholes are utilised. In others, long distance outfalls have to be constructed. A feature of the fenlands is the large scale drainage works that have been carried out in the recent past, these include the diversion of the Great Ouse River into man made "cuts" and the construction of large drains such as the Bedford Level and the Hundred Level Drains. The drainage problems are compounded by the fact that some areas of· Norfolk are below sea level and drainage is by pumping, as is evidenced by the large number of windmills which were used for this purpose before the introduction of electrical power.

Case Studies

A number of schemes that have either been constructed, are in the process of construction, or at the design stage, will be described. These will serve to illustrate the types of problem that arise. The locations are shown in Figure 1.

(i) King's Lynn Southern Bypass

This has proved to be the most complex scheme constructed in the County, due to it being situated almost entirely on typical fenland deposits. The geology of the area is briefly as follows; underlying the Quaternary strata is Kimmeridge Clay, above which are superficial, or drift, deposits, consisting of glacial material, post-glacial to Recent alluvium and peat. The natural deposition of these materials has been compounded by artificial means arising from such activities

Figure 1. Location of highway case studies, in relation to geology.

as reclamation works dating back as far as the Roman era. The most

recent examples being the diversion of the Great Ouse River into

channels such as the Eau Brink Cut constructed in 1821.

A simplistic sequence, as revealed by boreholes, is a three

layered structure consisting of finely bedded clayey silts and fine

sands, fen peat, and silty and organic clays (generally soft), over-

lying Kimmeridge Clay. The total depth of these materials being

some 13 m to the western end and gradually decreasing west to east to a

minimum of 3 m. Generally the peat layer was found to be between

1.5 and 0.5 m thick, although it appeared to have been eroded away

in places at some time in its history, and was generally lying at

ordnance datum level some 3 m below ground level. Inclusions of

glacial materials ranging from boulder clays to gravels were observed

within the lower layer. The Kimmeridge Clay is generally a stiff

to hard grey laminated and fissured silty clay containing shells ,

shell fragments and fine gypsum crystals, the latter occasionally

being found in layers. Beds of bituminous clay occur, usually

recognisable by their dark brown colour and waxy appearance, and

bands of hard claystone or mudstone can also be found. The upper

part of the Kimmeridge Clay is often weathered to about 3 metres below

its top surface, the weathering being usually recognisable by a

mottled brown coloration. The main effect of this weathering is a

reduction in strength. Highly weathered clay showing signs of

reworking was also found.

The results of the various tests carried out during the site

investigation showed a considerable variation in parameters along the

length of the job, to such an extent that different constructional

techniques were suggested for comparatively short lengths of the

scheme. These methods included the use of sand drains, two stage construction with a long consolidation period between stages, single stage construction with batter slopes at various angles along the route, the use of berms, surcharging, removal of unsuitable material and filling adjacent lowlying areas. The major problems were associated with stability and consolidation of the low strength, highly compressible material, under the loads imposed by the high embankments necessary for grade separation. In order to test various techniques a trial embankment was constructed, a section of which was deliberately failed. The results, when analysed, led to considerable savings on the cost of the scheme. Extensive monitoring of the behaviour of the alluvial deposits was adopted during the construction and reading of the instruments is being carried on for several years yet, as there is much data to be obtained from this scheme that could be utilised in the design of other schemes. The cost of the monitoring has also been recouped several times over.

A method was developed from the trial embankment data, for giving an indication of the approach of an embankment failure. Several such indications were observed during the monitoring of the main works and filling was successfully stopped before failure occurred - except on one occasion when a localised section failed between lines of instrumentation. The method is considered to be suitable for similar soft materials.

A further complication in the design of the scheme was for the foundations of the Great Ouse River Bridge. Some 200 m upstream of the proposed bridge site a slip had occurred in the flood bank of the

Eau Brink Cut (Skempton 1945), and as the general land level of the King's Lynn Area is below that of mean high water level, the River Authority was concerned about the consequences of a failure of the river banks caused by the bridge works. Due to problems in constructing bored piles in the Kimmeridge Clay it was considered necessary to use a driven pile, which gives rise to problems of vibration during driving. As a number of the various layers found within the Kimmeridge Clay acted as channels for ground water under some considerable pressure, it was considered vibrational problems were easier to handle than dealing with water under pressure in a deep borehole (the Kimmeridge suffers from a considerable loss in strength due to softening in the presence of water). In the event this proved the correct solution, as several piles, after being driven during the actual construction, had water seeping up between the clay and the pile face. To reassure the River Authority as to the feasibility of such a proposal, a piling trial was carried out, monitored by piezo- meters and inclinometers. The piles were prebored to below a gravel layer within the soft alluvial deposits and the techniques used proved successful. It is interesting to note that during the main works considerable bank movements were noticed due to the tidal range. This created problems in monitoring the main pile driving which were overcome to the satisfaction of River Authority, contractor and County Council.

Compounding the problems of the earthworks was the fact that the route followed the disused line of the M. and G.N. railway, the embankments of which were of insufficient width to accommodate the new highway. Therefore problems of differential consolidation also

occurred. Bridges had to be designed to allow for settlements or

special treatment given to the design of the approach embankments,

by, for instance, the removal of unsuitable materials in the vicinity

of the abutments or applying slip coatings to piles or the backs of

abutments and wing walls.

The bypass is now open to traffic after a three year contract

period and it will be interesting to see if the long term predictions

of settlement, based on the trial embankment data, actually occur.

(ii) Loddon Bypass - A.146

This bypass was opened to traffic earlier this year and was

constructed by direct labour with specialist sub-contractors for

such items as the earthworks, fencings, etc. It lies to the south of

Loddon and is some 3.75 km long.

The route crosses two streams, the River Chet and Loddon

Beck. The site investigation showed sands and gravels, boulder clay,

brickearths and peat, the latter being in the vicinity of the stream

crossings. Whilst the extent of the peat was limited, it was of a very

wet nature, which made the drilling of the boreholes somewhat

difficult. Moisture contents were measured in the 400-800% range.

It is these peat areas which created the major engineering problems,

and it is convenient to discuss each river crossing separately.

Dealing first with the Chet crossing, where the peat was relatively

shallow, some 3 m being indicated overlying firm, uniform, fine to

medium sands. It was decided to divert the river temporarily and

excavate the peat, backfilling with material excavated from cuttings

within the site - an excess of fill was available on this scheme which

is rare for road projects in Norfolk. The peat on excavation was

first spread on the adjacent marshes by the sub-contractor, who soon
found this was impracticable due to plant getting bogged down. The
peat was then spread on adjacent fields higher up the valley sides
with no problems. It is interesting to note that notwithstanding the
nature of the material a surprisingly dry excavation was obtained with
near vertical stable faces. The excavation also revealed that the
surface of the underlying sands had a relatively steep dip to the
downstream side of the excavation, a maximum depth of some 6 m of
peat being encountered. The backfill consisted of an uniform sand,
which was later re-excavated for a bridge crossing the final course
of the Chet. By the time the re-excavation occurred the water table
level had reinstated itself to just below the original ground level.
This coupled with the grading of the sand gave rise to quick conditions
occurring during excavation, and it became necessary to construct
a cofferdam around the bridge site which required constant pumping.
On the occasions when pump failures occurred the cofferdam rapidly
filled with water.

Loddon Beck, on the other hand, presented different problems.
Here the peat was much wetter than the Chet valley, in the 700-800%
range, and much deeper, up to 15 m. It was considered at design
stage that it should be possible to displace the peat easily. The
procedure was to excavate down to the underlying firm material, where
this did not exceed 3 m, and elsewhere excavate 3 m, replacing the
excavated material with spoil from the cut areas. This method
proved satisfactory until the firm base was more than 3 m, when
problems arose due to uplift of the base of the excavation under the
weight of placed fill. This uplift also revealed large quantities

of silt that had not been detected in the site investigation. Excavation of the peat ceased, and fill was placed directly on the original ground surface, keeping the slightly firmer crust intact for constructional purposes. This method created one or two localised problems, 'considerable heave of the original ground surface, equal to the height of the new embankment, occurred a few metres away from the main area of the works. This heave took its toll on the existing drains adjacent to the works, which necessitated remedial action to maintain drainage flows across the new road line. The final course of the Beck was amended from the design to allow an Armco culvert to be constructed in a position where the level of the firm underlying material was known. Again quick conditions occurred during re-excavation of the deposited uniform sand. The embankment was constructed to just above its final level, and tell-tales on the original ground level showed that this settled a maximum of $5\frac{1}{2}$ m in the first $3\frac{1}{2}$ months during construction. The embankment was surcharged about six months later. The delay was due to constructional problems. Unfortunately it was only possible to maintain surcharge for about $3\frac{1}{2}$ months, but during this time a further 3.5 m of settle-ment occurred, and settlement of the finished road is still occurring, albeit at a decreasing rate (150 mm in 8 weeks at end of 1975), and it is anticipated remedial works will ultimately need carrying out to re-instate a smooth curve to the vertical alignment. During construction of the embankment a longitudinal crack about 30 m long occurred overnight, and one half of the embankment was found to be some 750 mm below the other half. What was described appeared to be a circular arc type failure, but the site staff felt that it was due to

a failure of the stronger crust, and carried on filling in view of the fact that a displacement technique was being used. In the event no further problems arose.

The brickearth caused problems for the earthmoving contractor as he chose to attempt to move it after a particularly wet spell, which was unavoidable, as all slack in the earthmoving programme had been used up. The natural moisture content of the material found during the site investigation was of the order 17-19% with a plasticity index 15 to 17.

(iii) Cringleford Bypass

This is a bypass of the A.11 on the outskirts of Norwich. The sequence revealed by the site investigation comprises Chalk, overlain by Crag deposits consisting of gravels and sands. The River Yare traverses the route, and associated with the river valley are alluvial deposits and peat. The problems associated with the construction of an 8 m high embankment on these latter deposits were overcome by excavation, and replacement by true free draining material excavated from the adjacent new Broad on the U.E.A. campus. This material was also used to make up the shortfall in the cut and fill balance.

Generally, few problems associated with the Quaternary deposits occurred during the construction of this bypass, although in the Crag deposits of the west bank of the river valley quick conditions arose in the construction of deep trenches for a replacement sewer. The deposits in this area were an almost uniform fine sand, and a natural high water table level was encountered. This problem required close sheeting and only a single pipe length of trench open at any one time.

It was necessary to relay an electricity main cable across the

new route at an early stage of the contract, and as that section was

ultimately in cut, a 9 m deep trench was excavated with battered sides.

This was in the Crag deposits, and it was interesting to see a virtually

perfect grading of material from coarse gravel at the top of the

excavation to a very fine sand some 9 m below.

The Chalk, as found at Cringleford, presents some problems for

the engineer. The Chalk is a very soft material, with a moisture

content at or very near its saturated moisture content. This makes the

material difficult to sample and to subsequently rehandle, as the

material behaves in a thixotropic manner, and in sampling becomes

further remoulded. It is considered that during the geological

history of the Chalk extensive restructuring has already taken place

under glacial action, either by frost action or even by complete

redeposition. The slurrying-up that occurs when the chalk is being

worked as a fill material gives rise to delays, unless the material

is kept at a moisture content below its saturation point. Problems

also occur during pile driving, as the dissipation of the driving

energy activates the thixotropic nature of the Chalk, and it is not

possible to drive piles to a set depth. A suitable length for the

pile has to be determined by pile tests and experience. The Chalk

also contains flint nodules which give rise to minor problems.

(iv) Potter Heigham

Potter Heigham bypass was constructed in 1969, as part of a 6

mile long improvement, which for most of its length utilised the

disused M. and G.N. railway line.

At Potter Heigham the bypass crosses the Thurne Valley, and, as

part of the preliminary investigation, a trial embankment was construc-
ted to test the in situ performance of the foundation materials. The
site of the trial length of embankment was to the east of the river,
where the line of the disused railway diverges from the line of the
bypass. Here the strata consists of 10m of soft grey silt, overlying
1 m of fibrous peat, which in turn overlies dense sand and gravel.
Instrumentation was confined to three sections, each with six piezo-
meters placed at various depths in the silt, with one plate settlement
gauge on two of the sections. To enable an estimate of differential
settlement to be made, one gauge was placed on the line of the rail-
way embankment, and the other on virgin ground. Prior to the commence-
ment of filling the old railway embankment was bulldozed away and
spread on the adjacent marsh. The rate of filling was controlled to
maintain a ratio of pore pressure increase to total stress increase
of 0.55, calculations having indicated that this was desirable to
achieve a factor of safety of 1.5 Filling ceased at a height of
3.6 m when a longitudinal crack appeared along a line ocincident
with the junction of the two embankments, this was seen to be due to
differential settlement, as there was no heave evident at the toe of
the bank. The estimated settlement after 22 years was approximately
0.43 m, readings on the settlement gauges showed 0.18 m and 0.55 m
respectively after 13 months.

(v) East Dereham

This scheme is at tender stage so it will not be possible to
give a full picture. It is included in this paper to give an
indication of possible pitfalls to the design engineer. The major

deposits indicated on the geological drift map are boulder clay,

overlying Chalk, with a few isolated alluvial areas associated with

streams. Knowing this there could be a tendency for the main

investigation to be confined to the alluvial areas, with a cursory

inspection of the boulder clay deposits. However, the site

investigation revealed that, on the site of a major bridge, artesian

conditions occurred, with a head of at least 3 m above ground level.

A second bridge site is also affected, to a lesser extent, by

artesian conditions, and the embankment level was raised to overcome

any problems.

A problem associated with the alluvial deposits, at a place known

as Scarning Fen is, as mentioned in the Introduction, the formation

of a suitable environment for rare flora and fauna. The Fen is a

site of scientific interest, being the habitat of Bryophytes - mosses

and ferns. Fortunately the route of the bypass only crosses the

northern boundary of the fen, where it is the home of old prams and

bicycles. The problem here is the construction of an embankment

which does not affect the natural drainage of the area, and the design

of a road drainage system which will not allow pollution of the fen.

The first objective will be achieved by the excavation of the fen

material, which at the point of crossing is relatively shallow, and

this will be replaced by a free draining material. The highway

drainage problem will be covered by a carefully designed and con-

structed closed drainage system.

(vi) Acle Slough

Immediately to the East of Acle village the A.47 trunk road crosses

an area of poor ground known locally as Acle Slough, which is largely
an active peat bog. Trouble has occurred for many years, over a
length of 240 m, necessitating frequent resurfacing to remove
irregularities. The strata consist of approximately 12 m of peat
overlying a mixture of sands, sandy clays, silts, etc., with what is
though to be Crag deposits at approximately 20 m below ground level.

In December 1963 considerable undulations appeared in the road
surface, which was immediately made up to level with 1600 mm of
crushed concrete and surfacing. Throughout the next six months similar
treatment, including making up the verge which was sinking more than
the carriageway, was carried out at approximately monthly intervals to
remedy the continuing failure which affected the southern half
of the carriageway. Settlements of the order of 0.25 m were common-
place.

In October 1964 an inspection revealed that what appeared to be a
reasonable road surface was merely a crust approximately 250 mm thick,
and beneath this was a crack with a top width of approximately 450 mm
and extending to a depth of approximately 5 m. Making up continued at
intervals until late 1965 when comparative stability was achieved.
It is estimated that a total of 7 m of fill was placed on the verge
during the operations, all of which disappeared into the peat.

In 1972 10 inclinometers were installed alongside the road to a
depth of 20 m, and pins driven into the road surface and levelled,
in an effort to detect any pattern of movement. Monitoring ceased
in 1974, when it was concluded from the results so far obtained, that
no real pattern had emerged. The scale of deflections obtained from

the inclinometers was small, and in some cases were within the
accuracy of the techniques used to survey the tops of the tubes at
each set of readings. The length continues to be resurfaced at
intervals to remove irregularities that still appear.

(vii) Acle Bypass

The route of the proposed bypass, which passes to the north of
the village can be conveniently divided into 3 distinct topographical
areas namely west of Fishley Carr, Fishley Carr and the Flood Plain
of the River Bure.

West of Fishley Carr there are two areas of low fill, a shallow
cutting, and the main cutting which attains a maximum depth of 12 m.
The soil conditions over this length show great discontinuity over
short lateral distances. A capping of boulder clay conceals sands,
sandy clays, and at depth (30 m below highest ground level, 18 m below
O.D.) the dense grey silty sands of the Crag deposits were encountered.
The engineering problems associated with this area are confined mainly
to the possibility of local seepages in the face of the cutting, and
the fact that some of the clayey sands constitute marginal fill as
defined by the Department of the Environment Specification for
Road and Bridge Works, i.e. natural moisture content exceeds plastic
limit x 1.2.

Fishley Carr is an area of soft amorphous peat (natural moisture
content 710%), varying in thickness from 2 to 10 metres, overlying 5 m
(maximum) of very soft silty clay. Crag deposits were encountered
beneath the silty clay. Here the water table is at ground level, and
as the Carr is an area of scientific interest, the Nature Conservancy

have asked that the level of the water table remains unchanged. At

the present time the intention is to displace the peat by surcharging

the embankment, which is to be of free draining granular fill.

East of Fishley Carr, the route crosses the Flood Plain of the

River Bure until it rejoins the A.47 east of Acle. Throughout this

length the soil conditions are fairly consistent, being approximately

18 m of soft silty clays overlying Crag deposits of dense grey silty

sands. A layer of amorphous peat, (natural moisture content 415.)

occurs between levels of approximately 5 m and 7.5 m. Recent shallow

boreholes along the line of the A.47 confirm the existence of the

peat layer to within 1 mile of Great Yarmouth. The low shear strength

and high compressibility of the silty clays give rise to the main

engineering problems on the scheme, those of stability and settlement.

Preliminary settlement calculations have indicated that up to

0.6 m of settlement could occur under a one metre high embankment.

Values of m_v and more particularly C_v show a degree of scatter, and

the magnitude of settlement, and the time for it to take place,

remain uncertain. Further investigations are being made, since the time

factor concerned can obviously affect the contract period chosen.

Stability analyses based on in situ vane strengths (mean c_u, 10 Kn/m^2)

show that a maximum height of embankment of 2 m could be achieved using

common fill and 1 on 2 side slopes. The intention, therefore, is to

keep the embankments as low as possible (maximum height 2.5 m) and to

use light weight fill in selected areas. Because of these problems

a 220 m long viaduct will be required to carry the A.1064 over the

bypass.

NORFOLK SANDY BEACHES: APPLIED GEOMORPHOLOGY AND THE ENGINEER
(a summary of the Presidential Address for 1975, delivered 13 October 1975)

K.M. CLAYTON*

Introduction

The coastal zone of Norfolk is geologically the youngest feature of the County, and certainly the most active. We may estimate that 95% of the solid material eroded each year is lost by marine action, and even if we include material carried by the rivers in solution, the coastal share of total denudation is about two-thirds. We know almost nothing about the early stages of the Flandrian transgression, but the coast owes almost all its features to the changes of the last 5-6000 years when the sea has been very near its present level. The sea has, of course, been acting on a land with its own pattern of geology and relief, and the general outline of the coast, together with the occurrence in the coastal zone of relatively high or low land, is a function of the geological (and geomorphological) history of the land itself. Nevertheless, the Quaternary deposits of Norfolk are rather easily eroded by wave attack, and the coastline has moved relentlessly landward at about 1 km every thousand years in some areas, while elsewhere a belt of marshland and dunes up to 3 km wide has been created. In terms of area, the long term gains have more than balanced the losses, partly because far smaller sediment volumes are involved in the building up and out of coastal marshlands than in the destruction of high cliffs.

Worldwide, we have some evidence that the dynamic equilibrium

* School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ

characterised by modest rates of coastal change, appreciable areas
of long-term equilibrium, and a general predominance of land gains
over land losses may be coming to an end. Three factors are involved:
1.   the past 6000 years have probably seen the natural reclamation of
many of the really shallow coastal areas, and further outbuilding
of sediment will be slow or absent as deeper water is reached;
2.   at present sea-level is rising at about 1 - 1.5 mm/year, and this
encourages erosion and partially affects the building up of marsh
levels; 3.   in the last century or so there has been a great deal of
interference with the natural systems by engineers, and in so far as
they have been able to reduce coastal erosion they have affected the
natural sediment balance of these coasts.   It would be difficult to
determine the relative importance of these three factors, but in
combination they are leading to appreciable departures from the
dynamic equilibrium of the past 4000 years.   We need to add a fourth
consideration to the context in which we view the coast as applied
geologists, and that is the dramatic change in the number and the
expectations of those who choose to live in the coastal zone.
Until 150 years ago no-one lived near the coast who did not have to,
and they appreciated the hazard of their situation, usually adjusting
to settle on a relatively high, and hopefully stable, piece of land.
Increasingly, as the last few decades have gone by, more and more
people have chosen to live near the coast, either in connection with
the holiday trade or perhaps for retirement.   This new settlement has
colonised many areas liable to coastal flood or threatened by coastal
erosion.   Either the hazard has been unappreciated, or the assumption

has been that a technologically advanced country has the ability to defend us all against the ravages of the sea. We must examine this assumption to see whether it is a reasonable and tenable view of coastal defence in the last quarter of the twentieth century.

The process-response system at the coast is a short-term one with very different relationships to those normally the concern of geologists. It is possible to measure environmental variables over very short periods of time and to observe the immediate response of the beach sediment to a single breaker, or a single tidal cycle. This gives us the possibility of coming, in time, to a full understanding of the relationship between the energy inputs from the waves and currents of the sea, and the response, and thus the long-term changes of the beach system. This approach may involve the detailed measurement and time-consuming analysis of the breaking forces within a single wave, as is being studied by the Institute of Oceanographical Sciences. It may be tackled on a longer time-scale by generalising the 'weather' of a train of waves to the wave climate as it varies from one season or year to another, and along the coast with the variation of aspects (exposure) and offshore water depths. Both time scales are a legitimate basis for investigation, but the cause-effect relationships in each are very different. Since erosional problems that concern local authorities (or householders), and which are the traditional concern of coastal defence engineers, are measured in years or even decades, our own (practical) interest in the coast has involved studying relationship relevant to such time-scales.

Coastal changes and sediment movement

Although the coast, or parts of it, are undergoing continual and
often rather substantial change, we possess remarkably little long-
term data. The main source of information has been old maps, and
where these have been carefully surveyed (effectively since the
introduction of the six-inch, 1:10,560, scale in 1880) they give
us information on the total retreat or advance of the coastline.
Resurvey has been infrequent (although less precise revisions have
been more common), but since 1945 air photography has been used on
a regular basis and for any actively-changing coastal area there
are usually at least two or three sets of photographs of great value
for monitoring change, although several may be of lesser value
through being taken near to high water. Survey of beach profiles has
been limited to occasional research projects or to particular occasions
when coast defence works were being planned. Attempts to measure
sediment movement have been even more infrequent, and we have hardly
any cases where a complete sediment budget involving onshore-offshore
movement as well as littoral drift has been measured. There is no
doubt that the design of coast defence schemes is disadvantaged
by this paucity of historical data, and it is impossible to acquire
it in the short period allowed for the planning and installation
of new coast defence works. One of the objects of our current
research is to acquire a run of such data and to establish the
feasibility of setting up a beach monitoring system.

The contract from the Department of the Environment requires
82 beach profiles to be surveyed every three months. These give us

a good deal of information on seasonal and longer-term changes in beach volume, and should also allow a selection of significant profiles to be made that can be surveyed on a continuing basis, hopefully by the responsible local authorities. In addition we have attempted to calculate littoral drift of sand through the beach by using volunteer observers to record the height and angle of approach of waves. Coupled with a check (by using fluorescent sand as a tracer) that the American empirical formulae apply to Norfolk beaches, these data have allowed computation of littoral (sand) drift values for eight sections of the East Anglian coast. From these values an initial, and still unsubstantiated model of coastal sand transport has been produced (Figure 1). We are currently examining these data further and comparing them with estimates derived by other methods.

We may pause here to note that the model excludes both mud and shingle. McCave has recently discussed the mud budget for the North Sea. About 1/3 of the sediment contributed from erosion of the Norfolk cliffs (i.e. about 250,000 m^3/yr) is mud, and this is quickly moved away by tidal currents. No drifter releases have been tried from the area offshore of these cliffs, but it seems most likely that the mud that does not move offshore into the North Sea 'sinks' is deposited in the estuaries and on the marshes of the Essex coast. Mud accumulation in the Wash is not large (and may be in part the result of local redistribution), and drifter movements suggest that it may come from the Holderness cliffs rather than from N.E. Norfolk. Rates of mud accumulation around the Norfolk coasts have not been measured very carefully, but if the North Norfolk marshes were simply to keep
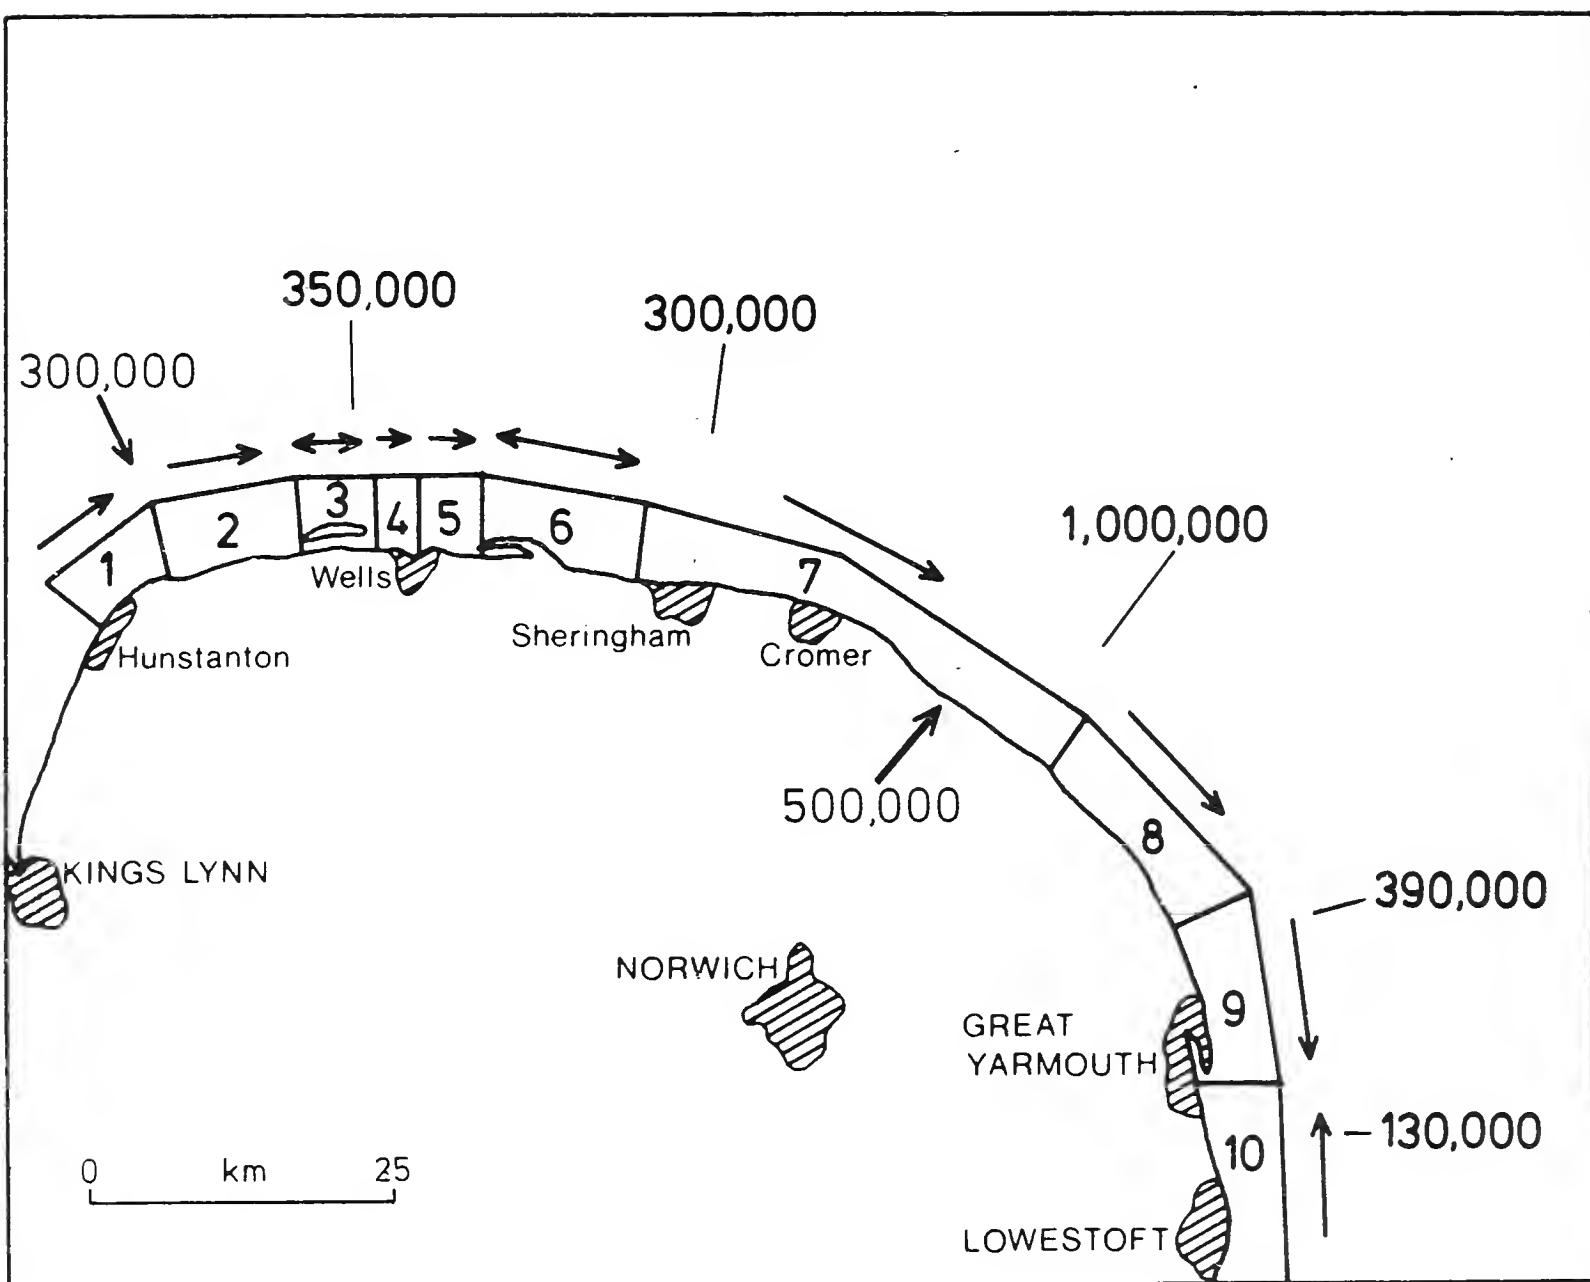

Figure 1. A model sand budget for Norfolk beaches (after Cambers).
(Values in cubic metres per year)

The system suggested here has two inputs: from offshore in the
northwest, and from the eroding cliffs. Computed net rates of
movement for five points are shown. Offshore movement is
not quantified but is implied by the littoral drift values
and will be located at the cell boundaries shown.

pace with rising sea-level, the annual increment would be of the
order of 100,000 m^3.

It has often been suggested that most of the shingle along the
coast was placed in position by converging wave trains as the Flandrian
transgression worked across the continental shelf. It is of course
still reworked by contemporary waves and currents as the migration
of Orford Ness shows, but this concept suggests that contemporary
supply is not an important feature in the maintenance of these shingle
beaches. In Norfolk the most important of these features is the
long shingle ridge from Weybourne Hope to Blakeney Point. This
ridge is slowly being moved landward by wave action at just under a
metre each year on average. Its form, with the spit at Blakeney,
suggests westward transport from the cliffs at Weybourne and beyond.
The wave observer data of 1974/5 strongly support a net eastward
transport of sand along this section of coast, and it has been
suggested that the balance of the higher energy waves required for
significant shingle movement might shift the shingle in the opposite
direction. However, recomputation of the data using a reasonable
threshold value shows that even considering the higher energies alone,
net drift movement will be eastward. Thus Blakeney Point may be
attributed to the realignment of an existing shingle beach and the
landward movement of the eastern end to match cliff retreat; it does
not fit the textbook version implying littoral drift towards the
point. Such eastward drift as has occurred has no doubt aided
rotation of the ridge towards a position more nearly normal to the
beach-forming waves, and as the ridge rotates in this way, the rate

of littoral drift will decrease. Present rates for sand are quite

low, and are probably very low for shingle; indeed were this not so

the feature could hardly have survived so long.

Three natural environments

Three almost natural areas of coast have survived in Norfolk,

two because they are accreting, one because until recently it was too

costly to defend. These areas have particular interest simply because

they are continuing to evolve geomorphologically and geologically

with little interference by man. Indeed it is worth stressing that

to the geologist and geomorphologist the naturally occurring

processes of the coasts are as worthy of protection through such

devices as nature reserves as are rare plants or birds. Indeed it

is hard at present to see how else an eroding coast might be

preserved, while even accreting beaches in natural condition are

increasingly restricted to coasts preserved from development for

quite other reasons. Since many of the features of special interest

in such reserves are connected with the instability of the natural

environment, it is clearly important to preserve all aspects of that

environment from improvement or development by man.

1. The barrier island coast of North Norfolk

Exposed as it is to the relatively long fetch from north to

south down the North Sea, this is a high-energy coast, rather closely

adjusted to wave attack, both in profile and plan. The coastal zone

is backed by an abandoned cliff-line and in front of this lies a

broad zone of marshes intersected by a series of tidal creeks and

more open bays. On the seaward side, beaches locally backed by dunes

break the wave attack at high tide, especially on the outer promon-
tories and on Scolt Head Island. Between these, and locally in front
of them, are very broad areas of intertidal sand. The marshes have
grown up in the quieter environment behind these beaches: levels
are generally low, and only at Holkham have appreciable areas been
reclaimed. The cliff has not been dated, but it is possible it dates
from the last Interglacial, like the related feature in Lincolnshire.
It is unlikely to be related, except in local detail, to the present
stand of sea-level, for that would have quickly built a series of
offshore bars and barrier islands, from which the present coast has
evolved. These features are still rotating into a position normal
to wave attack, as is shown by the exposed marsh clay on the beach
on the eastern end of Scolt Head Island. However, it is also clear
that taken as a whole the coast is almost stable, and at localities
such as Holkham Bay, progradation is occurring. Present changes are
best interpreted as a gradual simplification of the coastal plan,
increasingly possible as deposition reduces the flushing volume of the
tidal creeks and embayments. While the orientation of the coast
will eventually be controlled by wave attack, its position forward
of the abandoned cliff line reflects a shallow nearshore zone on
which the sands and marsh muds are lodged. We have no knowledge of
the geology of this shallow ledge, and it could be of Chalk or of
till. It deserves investigation.

Most of this coast is little developed, and planning controls
and protective ownerships are likely to keep it this way. In addition,
since most of the coast is stable or even prograding slowly, there is

no pressure for large-scale interference with beach processes.

Nevertheless, isolated areas of erosion or flood-hazard do occur,

as at the (1953) breakthrough on Scolt. Although some piles have been

driven into the beach at the breakthrough, and some attempts have

been made to promote dune growth, the situation is still nearly a

natural one. As far as flood hazard goes, the marsh perimeter banks

landward of the channel that separates Scolt Head Island from the

mainland are the real protection and these are not threatened even

on those rare occasions when the sea is high enough to split the

island in two. Wells Beach is a local problem related more to the

scour of the channel at its foot than to the general nature of this

coast. It is a sad commentary on current skills in coastal engineer-

ing that a beach with so much intertidal sand in front of it should

be so poorly nourished. The Salthouse shingle bank inevitably leaks

at high tide and is liable to be breached during a surge: so far it

has not been thought cost effective to improve it in any way.

One further feature of the North Norfolk coast deserves further

examination. Although there are sizeable dunes at several points,

there are other areas (e.g. Holkham Bay and Bob Hall's sand at

Wells) with very wide intertidal areas of sand backed by quite modest

lines of dunes. These are not attacked and rebuilt with any frequency,

so one is led to conclude that the rate of sand supply is low;

somewhat surprising in view of the huge areas exposed with each tidal

cycle. No measurements have been made, but it does seem that

these sands are rather slow to dry, either because of their

grain size distribution or because of a high water table. Indeed,
it is possible to envisage a situation where dune volume could aid in
the maintenance of a high water table on the beach and thus inhibit
continued dune development. Whatever the reason, these relationships
again underlie the overall stability of this low coast, despite its
exposure.

2. The cliffs

From Weybourne to Happisburgh and beyond, almost the entire
coast is cliffed. Short sections have long been defended, especially
at Overstrand, Cromer and Sheringham, but it is only in the last year
or so that a start has been made on defences below the high and
active cliffs between Trimingham and Cromer. Measured rates of
retreat on these cliffs show mean values of a metre or so a year for
the past 100 years or so, and we have no reason to believe that similar
rates have not been a feature of the 6000 years or so since sea-
level reached its present stand. In addition retreat rates are
independent of cliff height. While the immediate cause of removal
of material from these unstable cliffs is wave attack at the cliff foot,
continued recession through 5 or 6 kilometres can only come about
through an efficient system of sediment transport and the gradual
lowering of the entire offshore zone. In periods of rising sea-
level, as at the present, offshore lowering may be matched or
exceeded by the annual sea-level rise, but it remains a factor in
the maintenance of erosion rates over time.

Man's perception of this erosion and his understanding of the
reasons for it have not been very satisfactory. Few people who

live near these cliffs understand that despite the obvious signs

of failure where springs emerge, the sea is the ultimate cause of

the problem. One householder, driven out of his house by a huge slip

that took half of his front lawn, told a reporter that "it could not

be the sea causing the erosion because all the falls were at the

top of the cliff". Even the local authority, unsupported by central

government funds, has spent appreciable sums attempting to drain

the sediments that outcrop in the cliffs. They may steepen the

cliff and so gain a few years' breathing space at the top, but they

will not affect the inexorable attack of the sea at the foot. As

Dr. Cambers has shown, these cliffs contribute an annual average of

700,000 m^3 of sediment to the beach, 500,000 m^3 of it sand and

shingle. While some must move offshore, a high proportion moves

through the beach system where net littoral drift reaches a million

cubic metres a year from N.W. to S.E. Here is the efficient removal

system that we guessed must be the concomittant of sustained retreat.

Whatever the height of the cliffs, this littoral drift can dispose

of the sediment supplied with an efficiency that more than matches

cliff retreat. Indeed we are driven back to the hypothesis that the

ultimate control on the system is the offshore slope since this is

the overall control on the wave energy that may reach the cliff

foot.

Coast defence in such a situation, unless it can increase

beach volumes, is unlikely to succeed for long. Indeed, any reduction

in the rate of cliff retreat (and this has already occurred from

Mundesley to Happisburgh) by decreasing the volume of sand and stone

delivered to the beach will produce feedback by reducing beach volumes

and so stimulating erosion. Yet by attempting to stand firm at

such sites as Overstrand, Cromer and Sheringham, a.defenced headland,

undefended bay type of coast has already been initiated, and that

too cannot be stable for long. Finally, we may note the interest of

geologists and soil mechanics experts in the continued availability

of actively eroding cliffs, both for the exposures they reveal and

the slope failure forms they demonstrate so well. Resolution of

these divergent interests will not be easy.

3. The Nesses

At several points along the East Anglian coast gentle promon-

tories nose eastward into the North Sea. These low sandy features,

often backed by a .complex dune belt, are known as nesses. In Norfolk

Winterton Ness and Caister Ness are our only two examples, the latter

has migrated southwards to Yarmouth North Beach. At Winterton the

dunes and broad beach lie in front of a fifteenth century cliff, so

we have some idea of the rate of accumulation, while at Yarmouth North

Beach progradation has averaged almost 2 m a year since 1935 and is

still continuing. Over the years many theories have been put forward

to explain these features, most of them involving sand moving onshore

from the offshore bank systems, under the influence of waves and

tides.

Whatever refinements and corrections still need to be made to

the model of coastal sediment movement that was built up from the

wave observer network of 1974/5, the data are good enough to suggest

a radically different interpretation of the East Anglian ness

K.M. Clayton

features. It is observed that the computed value of littoral

drift north and south of each ness feature is rather different.

The different values result from the observed pattern of wave height

and direction of approach to the shore,but it will at once be seen

that the contrast north and south of each ness is to be anticipated

as the effect of the difference in overall beach orientation. Since

this part of the coast is already very oblique to any high energy

waves coming down the length of the North Sea, the pattern is for

drift north of the ness to be towards it,. and of a higher value than

the continuing drift away from the ness to the south. Thus as Dr.

Cambers has suggested, each ness represents a cell boundary in the

beach sand transport system, with higher values towards the ness and

lower onward values beyond it. While the difference in these two

values is available as sand feed to increase the size of the ness,

in practice quite a small proportion is added to the ness and over

90% of the feed is lost offshore. Thus these nesses are shown to

be zones of offshore removal of sand, and points at which sediment

is lost from the beach system. We do not yet possess good enough

techniques to measure the direction, let alone the amount of this

offshore movement, but only offshore removal is consistent with the

data we now possess on littoral movement (Figure 2).

Figure 3 gives the change in the length of defended coastline

over time. If we assume that the North Norfolk coast will remain

a natural area, it is clear that we are rapidly approaching the point

where the whole of the rest of the coastline will be defended. In
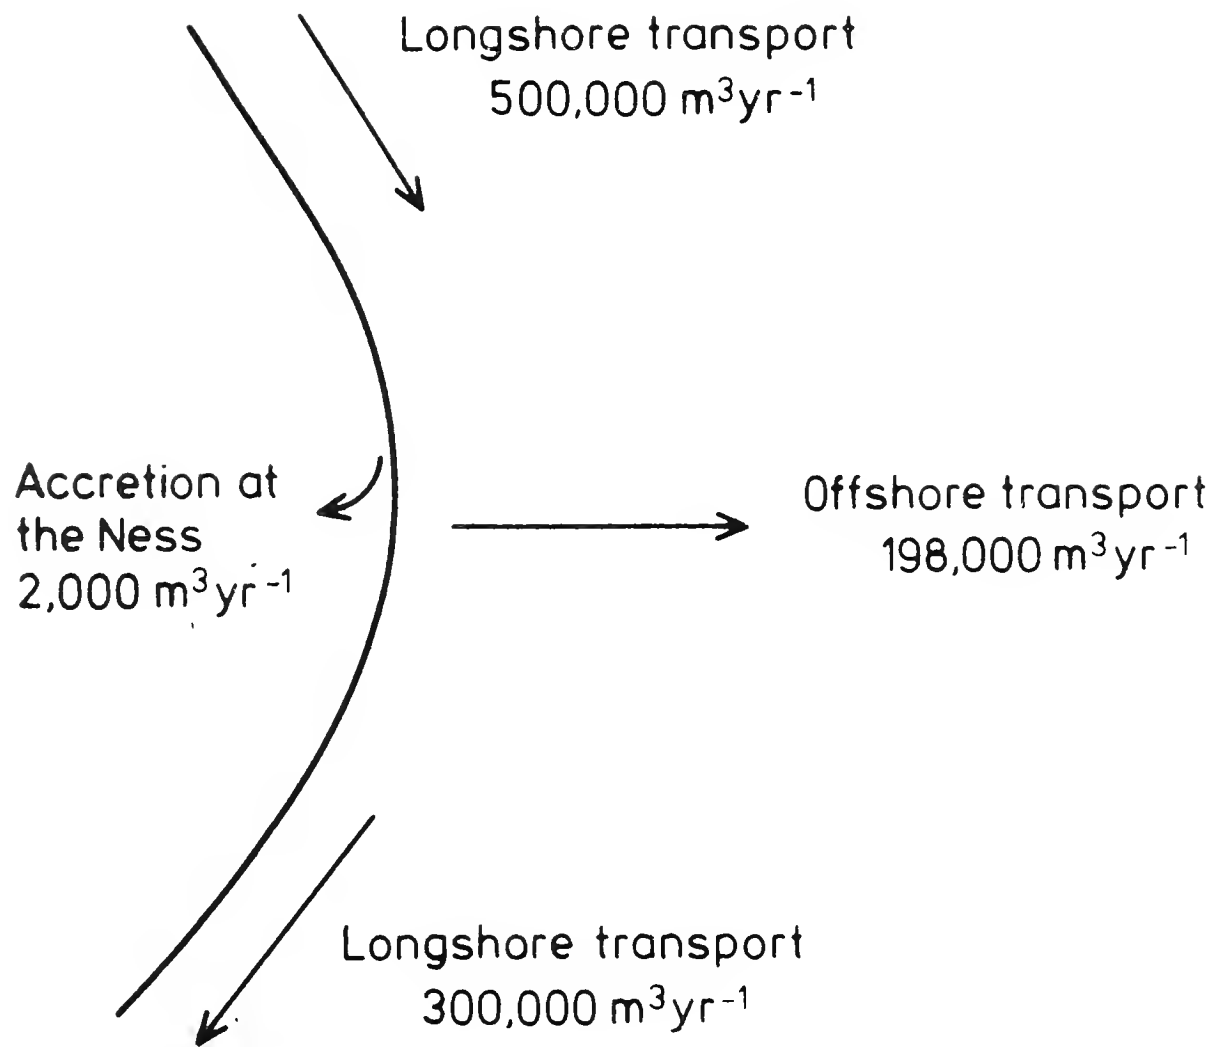

Figure 2. Hypothetical model of sand movement at Winterton Ness (after Cambers).

most cases this will be by engineering structures placed on the beach:
concrete sea walls, groynes, and wooden wave breakers. Responsibility
for these is divided piecemeal, formerly into even more authorities
than now, but even today the responsibility for coastal defence is
shared by the three coastal Districts of Norfolk and the Regional
(Anglian) Water Authority. There has been no grand design: Norfolk's
sea defences have just 'growed'.

It is not my purpose here to discuss the efficacy of these
various forms of coastal defence, let alone the costs and benefits
involved. Instead I wish to view them as intrusions into a mobile
geological landscape. They intrude of course as visible objects. A
few graciously-curved sea walls apart, they win no prizes for design.
Indeed if the sloping wooden barriers designed to break the force
of the waves before they reach the cliffs were sited anywhere else in
the natural environment there would be an outcry. Not only do they
intrude visually, they obstruct physically and greatly reduce the
pleasure of wandering across a beach at will. Yet they also intrude,
as of course they were designed to, into the dynamic system that is
the coastal environment. Littoral transport is reduced, and increased
erosion may ensure downdrift, as happened at Gorleston Beach when the
Yare training walls were improved, and happened in turn at the Old
Yarmouth Borough boundary where the Gorleston groynes ended. Even more
serious is the potential impact of even a relatively short-lived
cessation in coastal erosion. A glance at the model of sediment
transport we have built up shows only two inputs to the system.
One of these is assumed as necessary to balance the model and is from
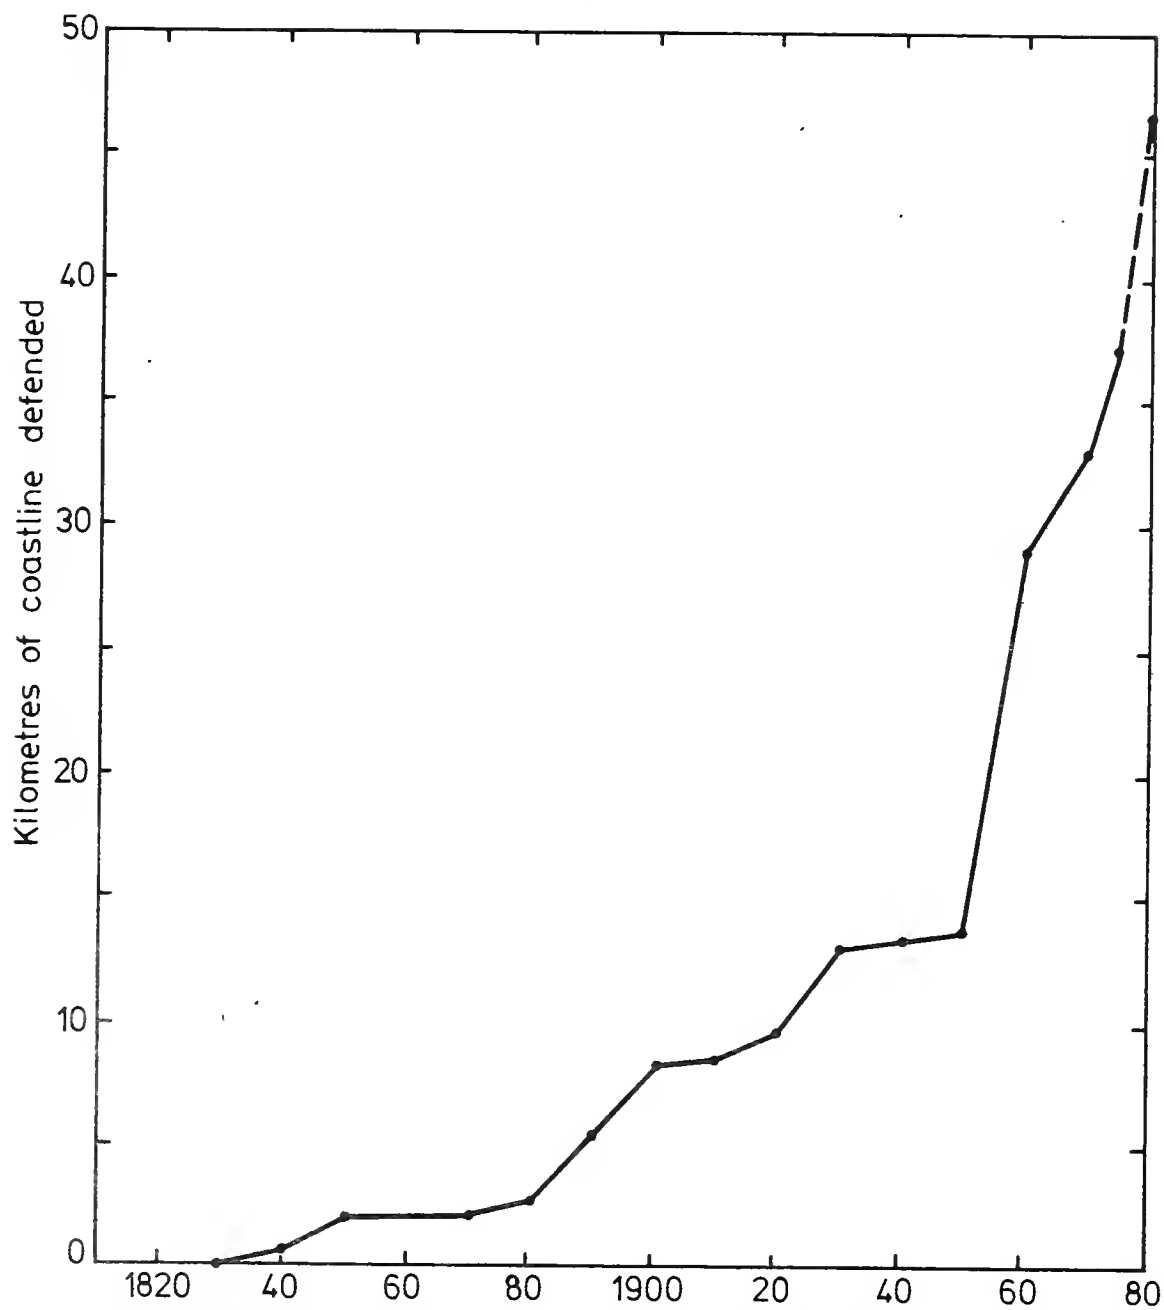

Figure 3.   Changes in the length of defended coastline (excluding
   flood banks) over the period since 1820.

Figure 4.   Coastal defences along the Norfolk coast (excluding flood
            banks)1975.

offshore or from the Wash subsystem. It is unlikely to be affected

by any engineering developments other than a Wash barrage.

The other is a measured input from the high cliffs, modified by coastal

defences over the last two decades, but still near to its natural

level. That input must be responsible for the sediment balance along

the whole coast from Happisburgh to Great Yarmouth. If it is cut off,

it is difficult to see how littoral drift levels can be maintained

without beach lowering and increasing erosion all the way to the

Yare mouth. Just as sediment trapped in Lake Nasser is no longer

contributed to balance sediment loss from the Nile delta, disturbance

of Norfolk's river of sand could be felt far from the source area at

Trimingham.

As geologists or geomorphologists this must disturb us. In the

long term it threatens the holiday beaches of the most heavily used

section of the Norfolk coast. Despite the larger units of our local

government system it still involves the classic problem of one District

taking action of profound significance for the authority downdrift.

The sooner our model of sediment movement is appreciated as a guide

to the impact of current policies, the sooner those policies will

be re-examined. It is not as if we have no alternative to pursue.

We must first stress the value of the sediment contributed by the

eroding cliffs, and the length of coastline benefited by it. If

we had to supply that sediment to the beaches ourselves, it would

cost us half a million pounds every year. Even its transport by

natural processes along 20 km of open beach, despite the loss of

half of it on the way, would cost something like £450,000 if we did

it by lorry. Finally, where we do require beach volumes to be increased this may be better done by beach nourishment - by adding sediment to the system - than by installing groynes and hoping for the best. The very beaches that are of value to us as natural physical environments are also of great value to holiday makers and deserve to be retained. And even geologists go on holiday sometimes!

Six lecture meetings were held during 1975: January (the Presidential Address for 1974), Mr. Hywell Evans on 'Aspects of the Glacial Geology of West Norfolk'; February, Dr. C.T. Baldwin, 'Tracks and Trails: Did Trilobites Wear Wellingtons?'; March, Dr. J.R. Cann, 'Plate Tectonic Processes at Mid-Ocean Ridge Crests'; October (the Presidential Address for 1975) Professor K.M. Clayton, 'Norfolk Sandy Beaches: Applied Geomorphology and the Engineer'; November, Mr. P.J. Lawrence, 'The Lower Palaeozoic Geology of the Oslo Region'; December, the Annual General Meeting followed by three geological films and members' slides. The March lecture by Dr. Cann was held at King's Lynn County Technical College. This is the first time that the G.S.N. has arranged a lecture meeting outside Norwich. It was judged a success and it is hoped such meetings will become a regular event in future.

There were three committee meetings during the year.

Mr. Norman Peake, who has held the office of Field Meeting Secretary for several years, has resigned from that position. I would like to record the Society's appreciation for all the time and effort that Mr. Peake has given over the years, not only in organising the annual programme of field meetings but in many other ways as well. I am glad to report that he will continue to help the Society in the position of Committee Member.

Other members who left the Committee were Professor Brian Funnell, Mr. Norman Sidebottom and Mr. Alan Fowler. Professor Funnell and Mr. Sidebottom have both finished a three year term, and Mr. Fowler has moved to Edinburgh. Grateful thanks are due to them for their help.

At the A.G.M. Mr. P.J. Lawrence was elected Field Meeting Secretary and the three new Committee Members are Dr. P.N. Chroston, Mrs. E. Evans and Mr. N.B. Peake.

EDITORIAL

Richard Joby has acted as our editor for some years and the Society owes him a considerable debt of gratitude for his excellent work in the production of the Bulletin. As new editor, I trust that the Bulletin will continue to serve the Society and all others who have a special interest in the geology of Norfolk.

In the production of this issue I wish to thank Professor Brian Funnell for his help and advice, Mr. Peter Scott for photographic assistance and Mr. David Mew for artwork.

Bulletin No. 30 will be issued in Summer 1978. Contributions should be sent to me as soon as possible, and no later than December 31, 1977.

Will contributors please note that manuscripts are acceptable in legible handwriting, although typewritten copy is preferred. In either case it would be a great help if details of capitalisation, underlining, punctuation, etc., in the headings and references (particularly) could conform strictly to those used in the Bulletin. Otherwise publication may be delayed.

Illustrations intended for reproduction without redrawing should be executed in thin, dense, black ink line. Thick lines, close stipple, or patches of black are not acceptable, as these tend to spread in the printing process employed. Original illustrations should, before

2

reproduction, fit into an area of 225 mm by 175 mm; full use should be made of the second (horizontal) dimension, which corresponds to the width of print on the page, but the first (vertical) dimension is an upper limit only. All measurements in metric units, please.

P.N.C.

DISTRIBUTION OF LOESS IN NORTH EAST NORFOLK

W.M. CORBETT*

Abstract

The distribution of a surface thin silty drift is plotted in north-east Norfolk between Norwich and the coast. To the south-west there is less than 20 per cent silt and to the north-east more than 30. Local variation in thickness in relation to ground surface relief is shown for a block of 480 borings on a 25 m grid at Hole Farm, Plumstead near Holt. The pattern, thick drift in valleys and re-entrants, thin striations on crests and none on steeper slopes has been strongly influenced if not caused by local movement.

Introduction

Soil mapping of O.S. sheets TG13 and 14 in 1968 and 1969 found a thin surface drift with more silt on all sites but the steepest slopes and the highest most exposed crests (Corbett and Hodge 1976). On flat uplands this drift is 40 to 70 cm thick and in valley floors and other concave sites up to 200 cm. In soil profiles a sharp textural change separates it from the underlying material. On the Cromer Ridge this material consists of gravels with less than 10 per cent silt, and in the lowlands to the south and east it is represented by the North Sea Drift (Norwich Brickearth), a loamy till with more clay and 20 to 30 per cent silt (Fig. 1, from Corbett and Tatler 1974).

* Soil Survey of England and Wales, School of Environmental Sciences, University of East Anglia, NORWICH NR4 7TJ.

Catt et al. (1971) studied its particle size distribution and
mineralogy at five sites in north-east Norfolk. The particle size
distribution was bi-modal with the main peak at 40 μm and a more or
less pronounced secondary peak at 250 μm. The silt fraction was
mineralogically similar to that of the Hunstanton till in north-
west Norfolk and to the loess at Pegwell Bay in Kent and they
suggested it was mainly wind blown derived by deflation of the
Weichselian glacial outwash. It was pointed out that this drift had
material, sand, clay and stones, foreign to loess and lacked some other
characteristic features. They referred to it as "Cover Loam".

Perrin et al. (1974) plotted zones in south-east England with
surface drift enriched by sand, silt and/or sand and silt; north-east
Norfolk, within zone IV, having sand and silt. Both the sand with a mean
particle size at 236 μm and a SE of 55 and the silt with a mean of 36.2
μm and a SE of 0.75 were considered aeolian, the sand being deposited
before or during the last intense periglaciation in the Devensian and the
silt later. They suggested that the present sandy silt topsoil was
derived by biological mixing and that the silt in Zone I, England south
of the Thames, had a geographic association with the loess in north east
France.

Veenstra et al. 1971 studied cover sand distribution in Holland and
Belgium on the basis of grain size and shape, found that grains above
400 μm are rare, only finer material being suited to wind transportation.

North-east Norfolk is an area of intense arable farming and a major
limitation to crop growth is lack of moisture in the growing season.
There is a mean deficit between rainfall and transpiration of about

150 mm (6 inches). The capacity of the soil to store moisture to offset
this deficit is related to particle size, in particular the content of
silt and fine sand. Deep silts are the only upland soils which avoid
drought stress and sandy soils without a silty surface are commonly
grass, heath or forest. For irrigation the soil storage capacity con-
trols frequency and amount.

This is a background study in the production of a soil map of the
County. Its aim is to plot the distribution of the silty surface drift,
"Cover Loam", at the regional and local scales.

General Distribution

Method. Samples from a depth of 35 cm were collected at the 114 sites in
east Norfolk and north-east Suffolk shown in Fig. 2. To avoid contami-
nation by local movement all were located on flat crests. 39 of these
sites were in three transects running parallel 2.8 km apart, from
Mattishall near East Dereham, north-east to the coast at Mundesley.
The transects, 37 km long were divided into 13 equal sections of 2.8
km and a flat crest site sampled in each section. At each site 9
samples were taken in a cross shaped pattern with an interval between
samples of 10 m. The transects were aligned at right angles to the
boundary given by Catt et al. (1971) and crossed it about one-third
of the way along their length. 55 additional sites were sampled, one in
each quadrant of every 2½" map to the north and east of Catt's boundary
including as well the sheets which lie immediately to the south and
west. At each site three samples were taken at the points of an equi-
lateral triangle with a 10 m side. The remaining 20 sites are those
soil profile pits on flat crests sampled in the detailed soil surveys
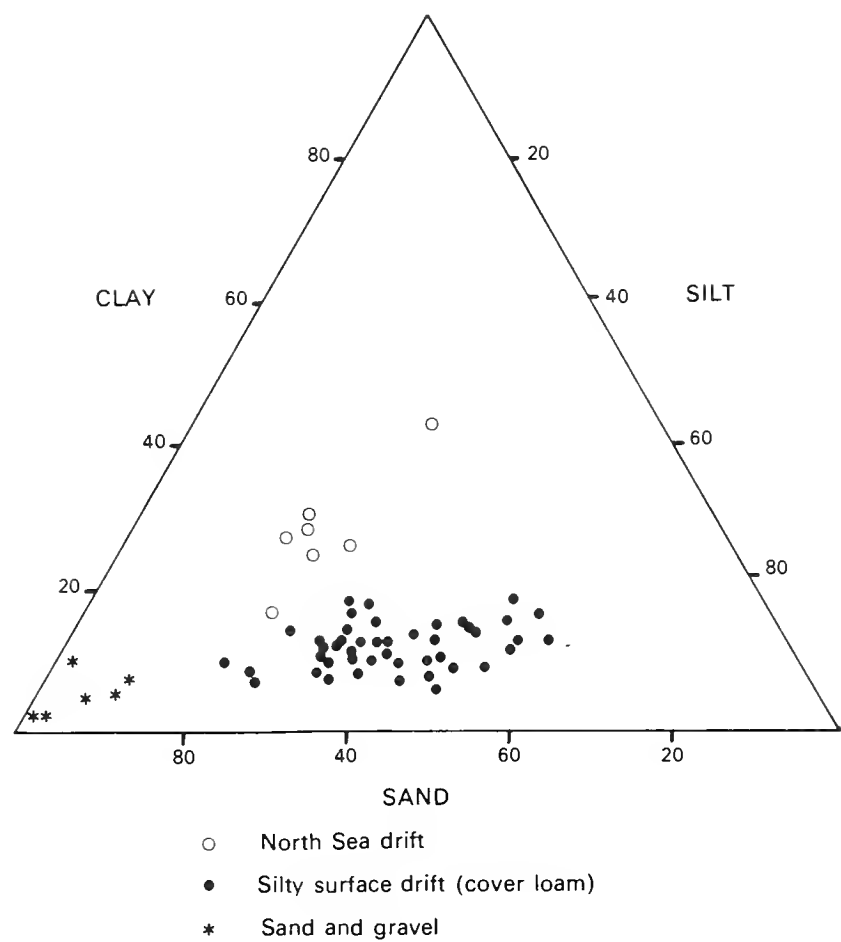

Fig.1   Size class fractions of drifts in north-east Norfolk.

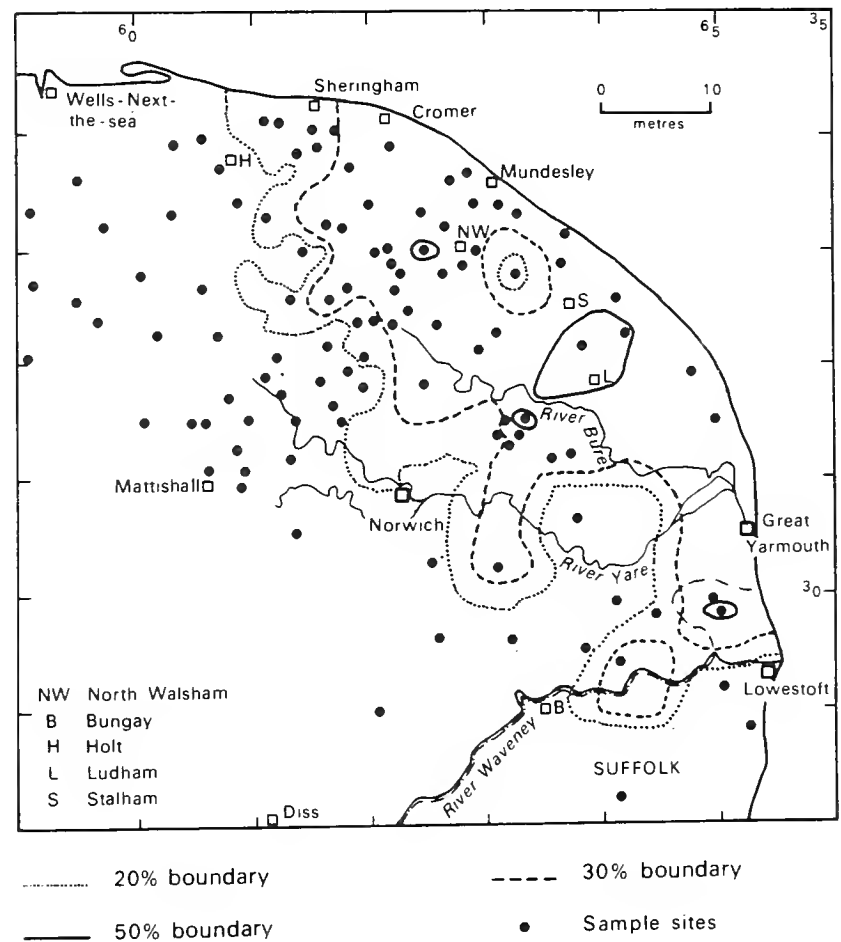

Fig.2   Subsurface silt in north-east Norfolk.

of 2½ inch sheets TM49, TM28, TG11, and TG13/14.

Particle size distribution in the fine earth (less than 2 mm) was determined on one or more samples from each site, using the pipette method after pretreatment with hydrogen peroxide to remove organic matter and dispersion overnight with Calgon (sodium hexametaphosphate). The fractions for all samples excluding the soil profile pits were, < 10 μm, 10-53 μm, 53-105 μm, 105-250 μm, 250-500 μm, 500 μm-1 mm, and 1 - 2 mm. The silt fraction in samples from soil profile pits is 2 - 50 μm.

Results. Fig. 2 is based on the printout of a SYMAP program for the 114 sample points. It shows a zone 5 to 15 miles wide running along the coast from Sheringham to Lowestoft with 30 to 50 per cent silt in the subsurface horizon of upland soils. Within this zone immediately to the south of Stalham and centred about Ludham is an extensive patch with 50 to 60 per cent subsurface silt and in three other localities there are small patches with this amount. To the south-east of a line from Holt to Norwich and Bungay subsurface silt is less than 20 per cent and within the 30 per cent zone there is a small patch between North Walsham and Stalham with this amount.

Transect data given in Table 1 and in Figs 3 also show the clear break between a north-east section with silt values above 30 per cent and a south-west section with values below 20. Within the silt zone eight samples at site A3 had a mean value of 41.5 ± 14.2 per cent and 9 samples at site A6 outside the silt zone a mean of 13.0 ± 2.0 per cent. The mean value for all transect sites within the silty area is 39.7 ± 7.5 per cent and sites outside 13.6 ± 3.6 per cent.

Table 1 Coarser sand (500μm–2mm), finer sand (105–500μm) along transects from Mattishall to Mundesley

The boundary is clearly expressed in Fig. 4 using the data from all 114 sites. Subsurface silt values rise from about 15 per cent to about 35 per cent across a relatively narrow boundary. In the transect data one site in each transect A4 (TG 142, 234) near Cawston, B2 (TG 198, 252) near Marsham and C3 (TG 191, 202) near Hevingham have values between 20 and 30 per cent. Fig. 2 shows that the transition zone is one to four miles wide. The direction of the boundary to the north of Norwich follows Catt's fairly closely but to the south it has additional lobes towards Loddon and Beccles.

Fig. 3 also shows along the transect the associated change in fine sand. The correlation coefficient for percentage silt against sand fractions movable by wind, 105-500 μm, gives 66.5 per cent of the variance accounted for. The correlation coefficient for coarser sand, too heavy for saltation, 500 μm - 2 mm, gives only 8 per cent of the variance accounted for.

The mean percentage of the finer sand for all sites within the silt area is 28.5 ± 9.5 per cent and outside the silt area 52.6 ± 10.4. The values for coarser sand are 6.3 ± 3.8 and 6.9 ± 3.3 per cent respectively. Across the silt boundary there is a clear decrease in the finer sand but little change in the coarser sand percentage.

The low percentage coarser sand suggests that the surface drift in both silty and sandy zones is almost purely aeolian. Soil profile pits on crests throughout the silt zone show that the depth of the aeolian surface drift ranges between 40 and 70 cm and its survival shows that biological mixing has been within this relatively thin layer. Three stage soil profiles of the same depth range with silty surface

Fig.4 Log curve percentage subsurface silt/eastings.

horizons unimodal in the 2 - 50 μm range, and sandy subsurface horizons

unimodal in the 200 - 500 μm range over a clayey till are common on

OS sheet TG31. Similar stratigraphic evidence at Great Blakenham,

Suffolk (TM 103503), is used by Perrin to post-date the silts and the

absence of cryoturbation features on silty sites to put the sand

deposition in or before the last intense periglaciation period in the

Devensian and the silts later.

Local Distribution

Method. Soil mapping of OS sheet TG 13/14 showed that the thickness of

silty surface drift varied with position in the landscape. The pattern

is expressed most fully on the southern boundary of the Cromer Ridge

where with a pronounced local relief of about 21 metres (70 ft), the

landscape has four facets, slopes of 5° to 15° on southern and western

aspects, flat crests with shallow re-entrants, narrow concave valley

floors and gentle 1^O to 3° slopes to the east and north. Silty

surface drift is thick on valley floors, absent from steep slopes and

thin on crests and gentle slopes.

Aerial photographs of the fields around Hole Farm, Plumstead, TG

114357, Plate 1, in 1970 and 1971 showed prominent growth patterns in

sugar beet and barley. The dark tones of better growth reflected

increase in available soil water on silty as opposed to stony and sandy

soils. The pattern appeared to delineate extremely precisely the

variation in depth of surface silts and showed that the understanding

of distribution from soil mapping was crude and generalised. A

network of thicker silty drift branched from dry valleys to re-entrants

and from there in thin trails up onto crests. The crests have also
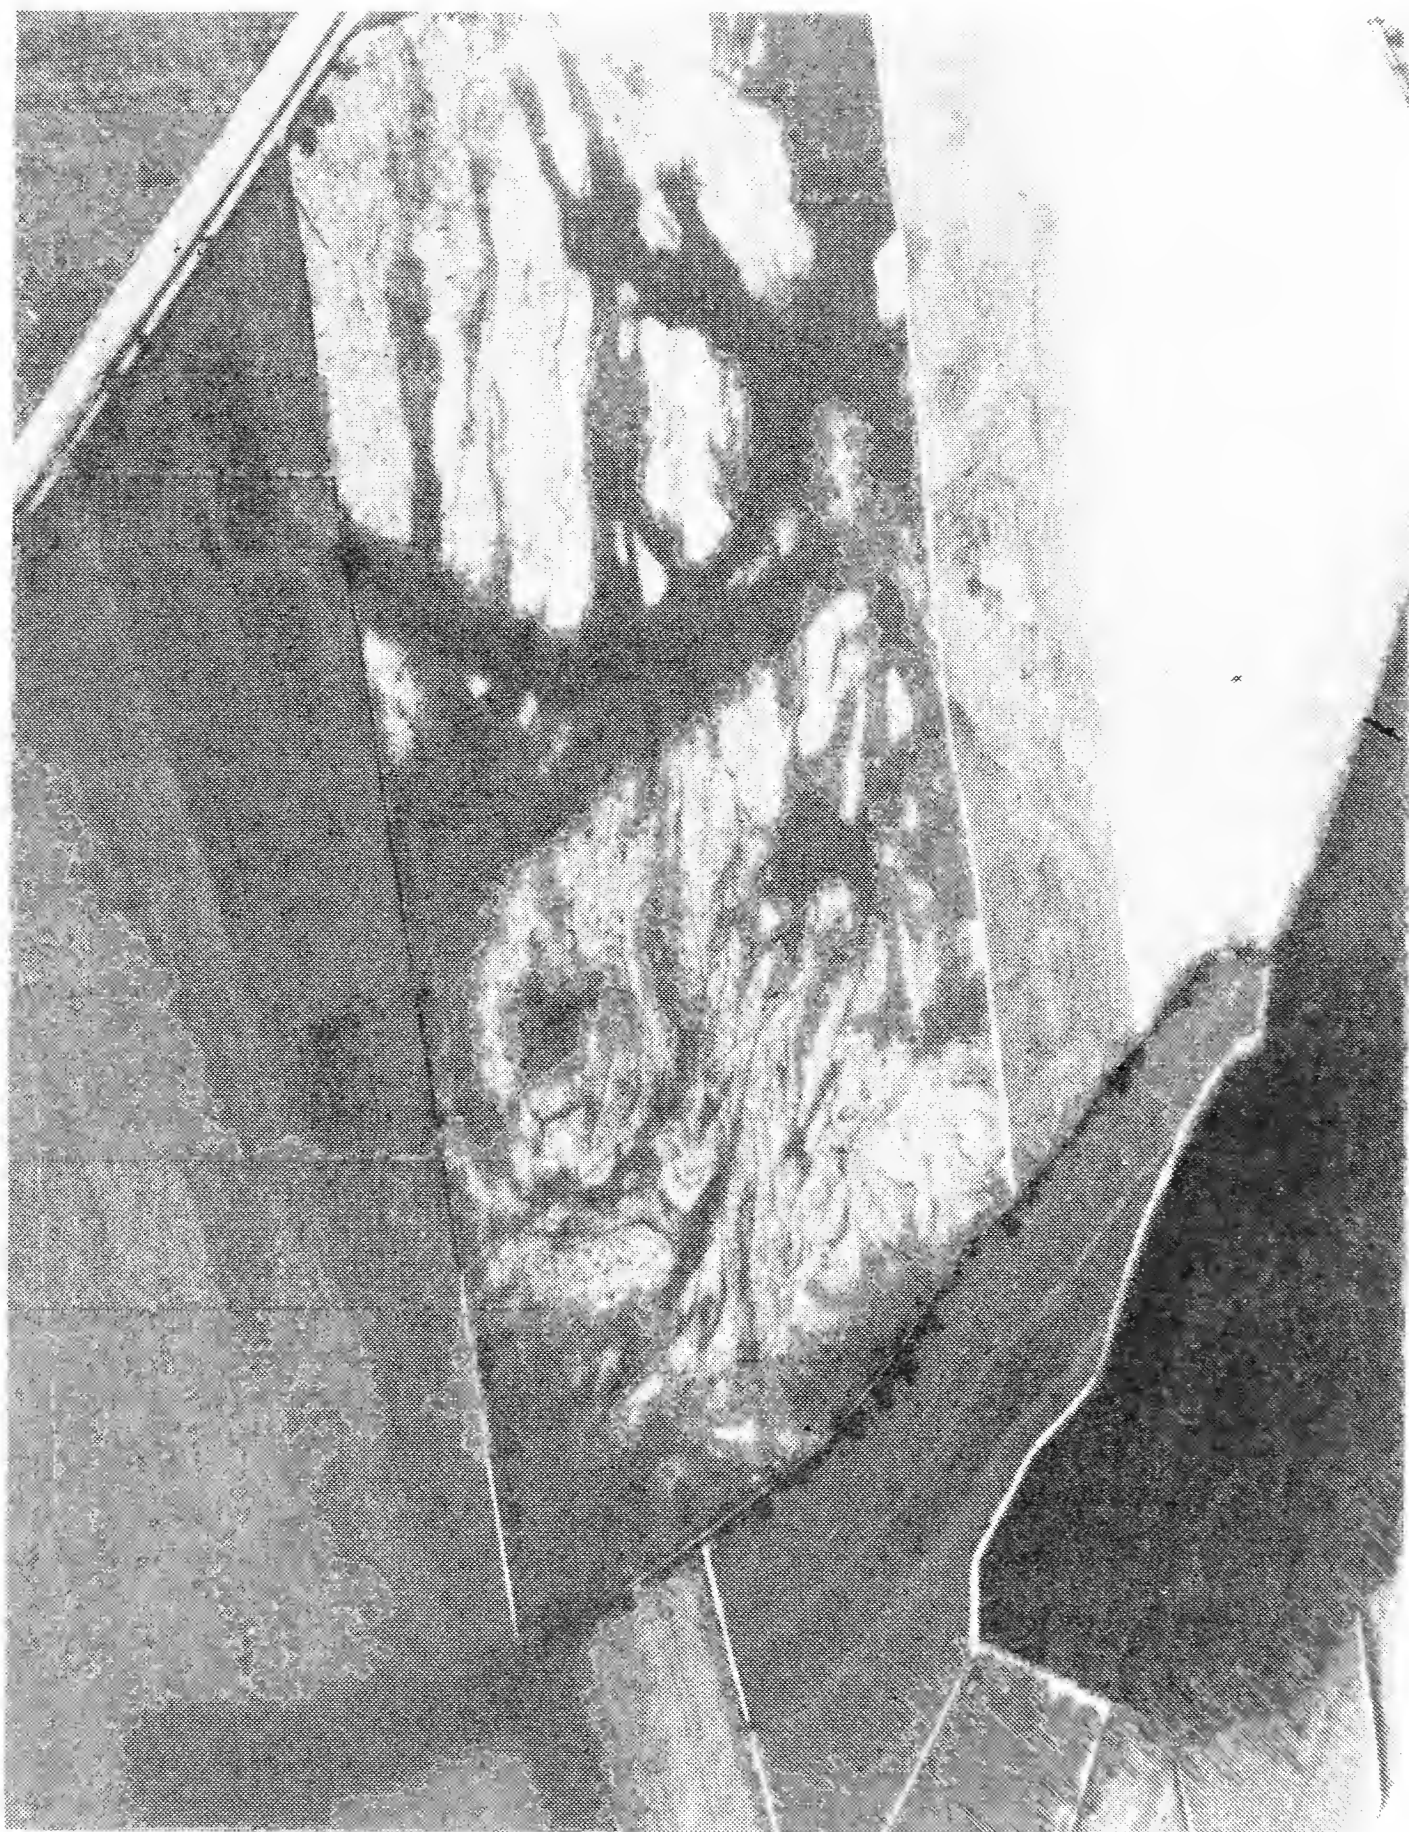

Plate 1 Sugar beet at Hole Farm, Plumstead, August 1970.

narrow irregularly distributed striations, a few metres wide, unconnected

with the heads of re-entrants.

This field was sampled in three ways.

1.   A block of 480 sites on a regular 25 m grid was pegged out to

cover the eastern half of the field in Plate 1. This block covered all

facets of the landscape. At each site the thickness of silty surface

drift, the depth to the textural discontinuity at the underlying gravel

surface was measured by hand auger and the site altitude by theodolite.

2.   A block of 93 sites on a regular 20 m grid was pegged on the crest

in the north west corner of the same field. The thickness of silty

surface drift was again measured by hand auger. This site was part

of an area contoured at 1/3 m photogrammetrically as an exercise by the

Geography Department of the University of Glasgow. This was used as

a base map.

3.   Four transects were located on aerial photographs to cross thicker

silty drift, at the highest altitude a narrow trail on the crest;

below the same trail as it connected with the head of the re-entrant,

below again in the re-entrant and finally in the dry valley. The sampling

interval along these transects was 10 m and at each site the thickness

of silty drift and the presence or absence of stones was measured by

augering. Site altitude was taken from the 1/3 m contour maps.

One site, site 10 on transect 3 Fig. 7, on the floor of the re-

entrant had silty drift more than a metre thick. A soil profile pit,

2 m deep to the underlying gravel was sampled and analysed for particle

size distribution by the pipette method.

Results. Fig. 5, the variation in the thickness of silty drift in

relation to local relief on the east side of the Hole Farm field was
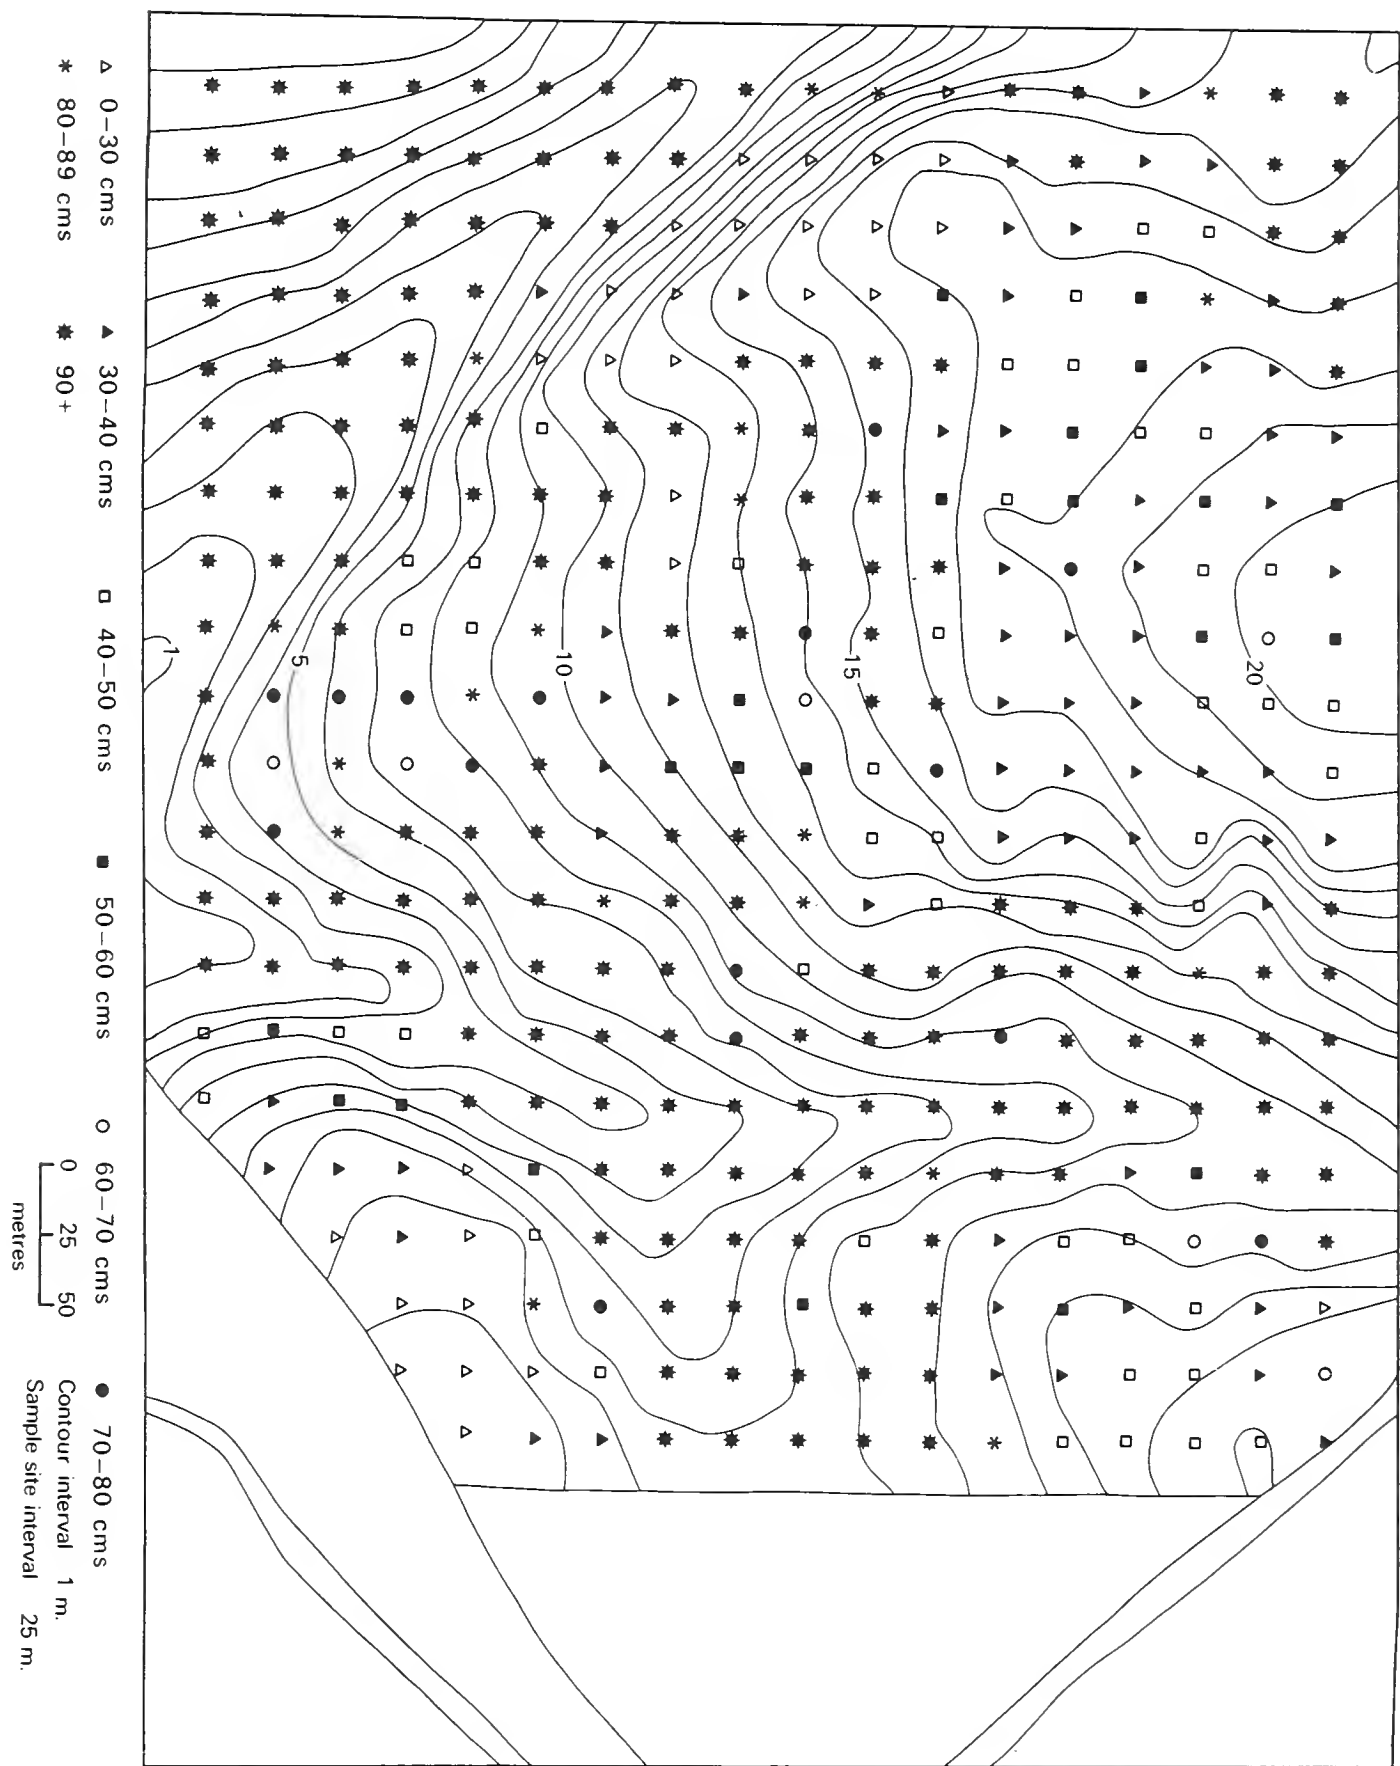

Fig.5 Thickness of silty drift in relation to relief at Hole Farm,
        Plumstead,TG 117 345.

made by superimposing 10 m interval ground surface relief contours

on the pattern of silty drift thickness produced by a SYMAP program

on the 480 sample points. The pattern is broadly similar to that found

in soil mapping but the relationship to relief is less exact. Thick

deposits extend from valley floors up onto quite steep lower slopes

and from the head of re-entrants in thin trails up onto crests.

Silty drift is absent from the steepest slopes and the narrower

crests. On crests, at least in the landscape sampled, there is no

extensive area with a uniform intermediate thickness of silty drift.

These observations fit the crop growth patterns on aerial photographs.

Using the 480 site data regression of thickness against altitude gives

only a percentage variance accounted for of 25.9 and against altitude

and slope of 28.7. The sampling grid appears too coarse particularly

for the pattern on crests.

Fig. 6 shows the local variation in thickness of silty drift on a

crest in the north-west corner of the same field using a 20 m sampling

interval. The sampling sites are marked by their thickness of silty

drift and the crop pattern has been transferred from an aerial

photograph. The mean depth of the good crop growth strata is 70 ±

23 cm and of the poor growth strata 46 ± 16 cm. Both strata have a

marked asymmetric distribution of thickness classes and the nature of

this asymmetry differs. Using the non-parametric Mann-Whitney U test

the difference in the range of thickness is sufficient at the 0.001

level. On aerial photographs the dark tones of better crop growth do

occur on the thicker silty drift and can be used to plot its distribution.

Grid interval 20m.
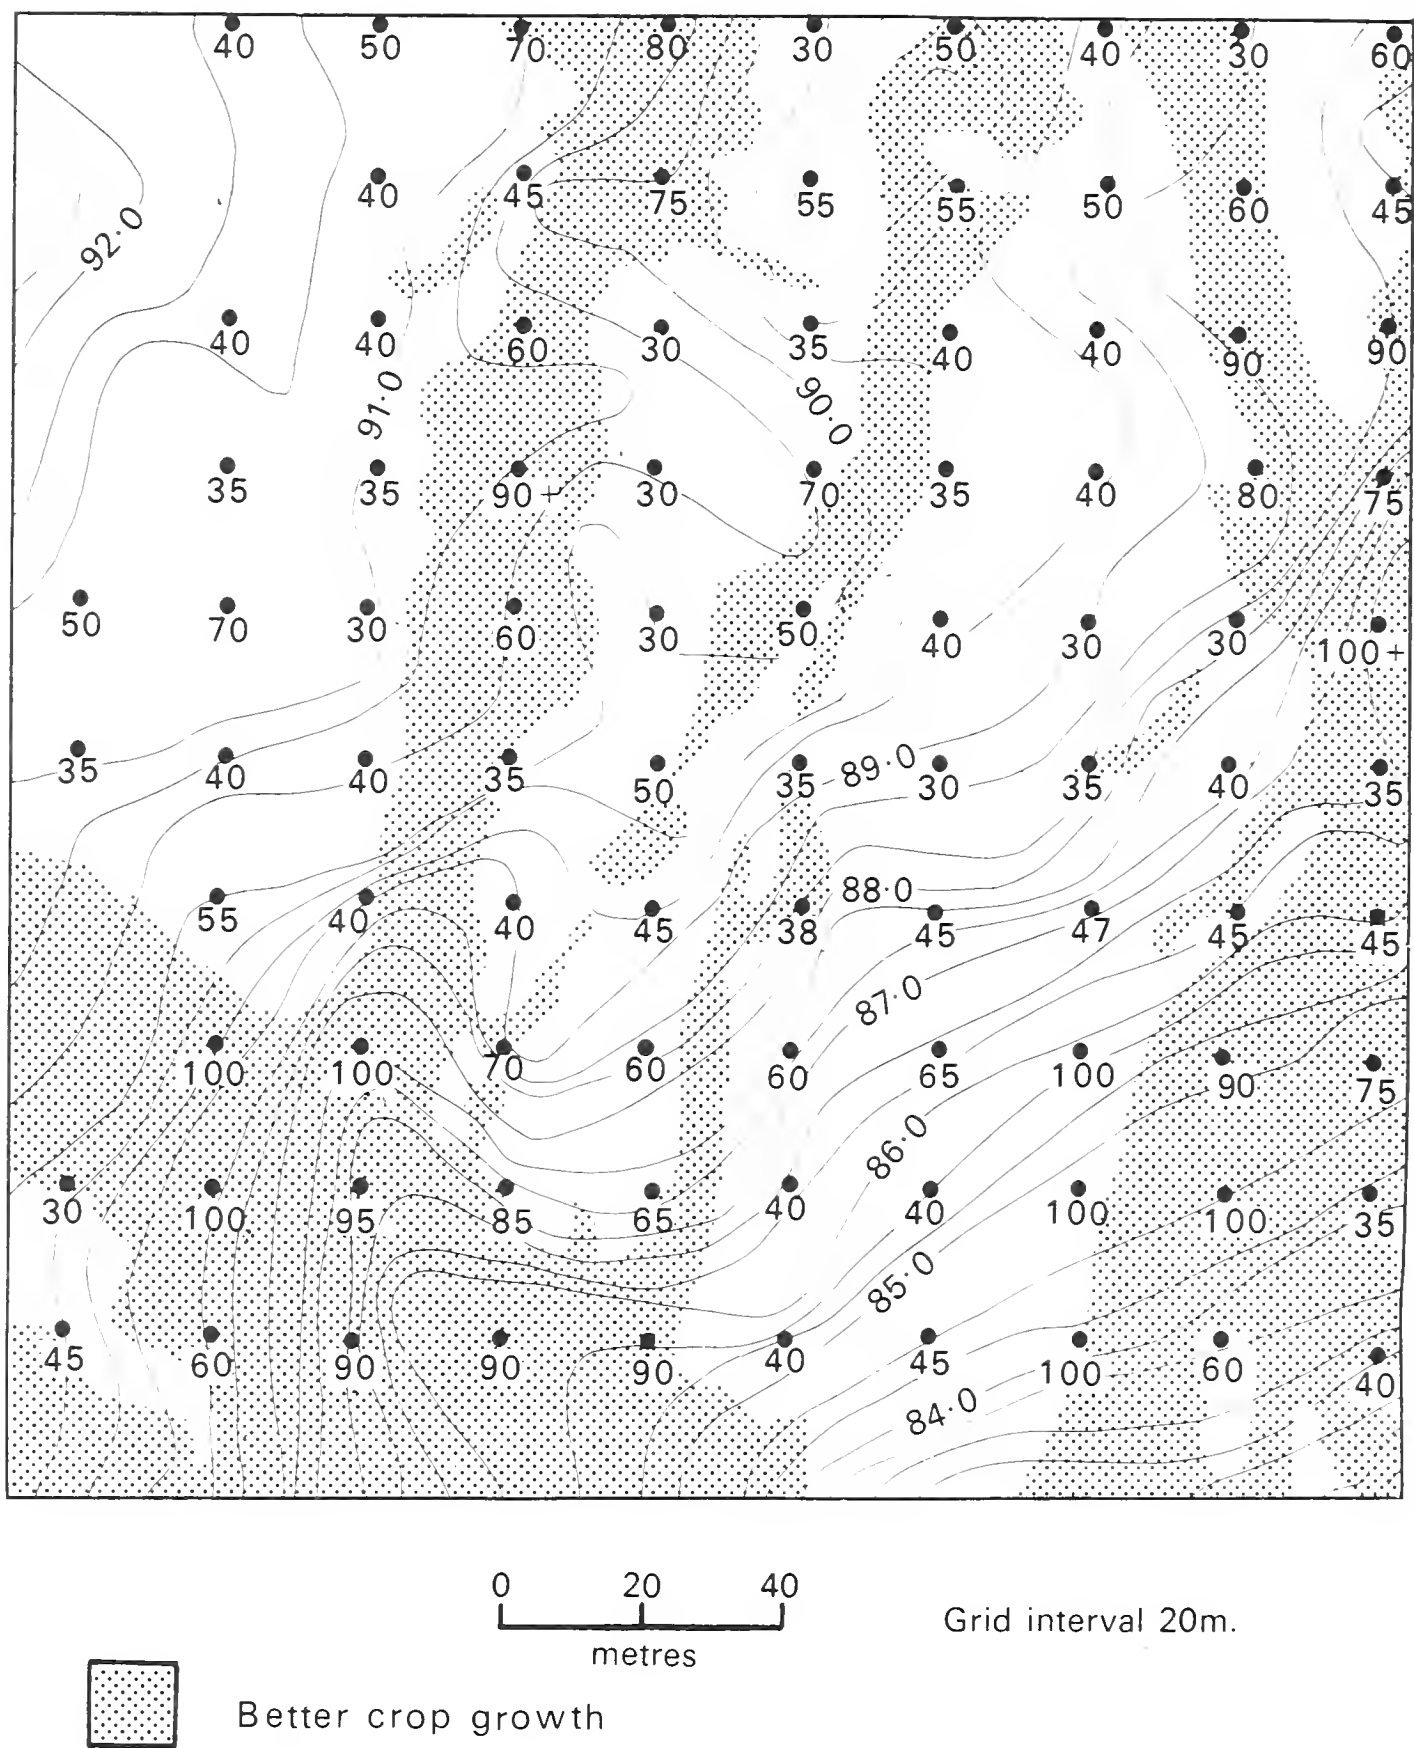

Better crop growth

Contour interval ⅓ m

Fig.6   Thickness of silty drift in relation to crop growth, Hole Farm, Plumstead, TG 112 236.

The origin of these thin trails of silty drift on crests is unexplained. Comparison of aerial photographs with 1/3 m contour maps shows some of them to be across flats and along slopes. Some also are isolated from the heads of re-entrants and some of those which are connected to re-entrants have wider apparently deeper sections away from the re-entrant head. The surface of the underlying gravels on crests is more uneven than the present ground surface and the trails could be regarded as an infilling with loess but the relief of the underlying gravel surface thus revealed in crop growth pattern is not a drainage network.

Four sections across trails of thick silty drift from crests to dry valley floor are in Fig. 7. The thickness on crests is 50 to 100 cm, in re-entrants about 2 m and on dry valley floors about 1 m. Stone-free drift occurs only at depth on the re-entrant floor and on the gentle north and east facing slopes of the dry valleys. Some small lenses of stone-free material are on steeper slopes above ledges or breaks in the underlying gravel surface. The silty drift in all other positions in the landscape contains stones incorporated from below during mixing or movement. The great bulk of the silty drift trails which in concave sites cross the landscape are trails of movement. In the centre of the valley floor there is a prominent gravel filled channel.

The particle size distribution in the 2 m pit profile in the re-entrant floor is shown in Figs 8A and B. The silty drift is about 190 cm thick and has three zones: 0-85 cm, 85-115 cm and 115-190 cm. The silt fraction in Zone 1 increases with depth from 55 to 68 per cent,

Fig. 8(b) Distribution of coarse sand and stones.

sand decreases from 37 to 20 per cent and coarse sand, above 500 μm,

from 5 to 2 per cent. Clay is about 12 per cent and there are some

stones. Zone 2 has more silt, less sand, variable clay, 1 per cent or

less coarse sand and no stones. Zone 3 has less silt but more clay.

Thin section micro-morphology shows Zone 1 to be poorly sorted with less

than 2 per cent illuvial clay and silt, Zone 2 well sorted with 3 per

cent illuvial material and Zone 3 less well sorted but with 6 to 8

per cent illuvial material. The colour pattern in Zone 3 is of

special interest. The general colour is reddish brown 5 YR 4/4

but this is broken by paler bands 10 - 75 mm wide, light brown

7.5 YR 6/4 set vertically or obliquely. The general impression is that

of peds separated by fissures of a paler contrasting colour. The paler

strips have more sand. This is taken to be a fossil soil horizon.

The profile is regarded as having a two or three stage history.

If Zone 3 represents a fossil soil horizon, Zone 2 is either its

surface soil horizons or a separate aggradation of loess laid down on

a truncated profile. Zone 1 represents local accumulation, solifluction

and erosion, the latter still continuing and the product becoming

increasingly more sandy as cultivation upslope cuts deeper into the

underlying gravels.

Conclusions

General

1. A zone can be delineated in north east Norfolk with more than 30
    per cent silt in the subsoil.

2. To the west and south is an area with less than 20 per cent silt.

3. Across the boundary there is little change in the nonaeolian fraction,

above 500 μm.

Local

4. There is a crude association of silty drift thickness with relief, thick in concave sites, thin in convex and absent from steep slopes.

5. On gravel the thickness pattern is revealed strikingly by crop growth in dry years.

6. On crests the pattern is narrow striations only some of which connect to the head of re-entrants.

7. Stone-free material is at depth in re-entrant floors and on gentle north and east facing slopes.

8. The pattern of thicker silty drift shown by crop growth is almost entirely mixed and/or transported material.

WHATEVER HAPPENED TO THE BOYTONIAN? A REVIEW OF THE MARINE PLIO-
PLEISTOCENE OF THE SOUTHERN NORTH SEA BASIN

P.G. Cambridge*

Introduction

Considerable confusion exists at the present moment due to attempts
to correlate a pollen dating system, based on borehole samples from
deeper water deposits, with shallow water outcrops whose stratigraphy
has been based on the molluscan fauna. The small samples and the
difference in facies in the borehole material does not allow for direct
comparison by means of the molluscs while the lithology and state of
weathering of the outcrops results in poor pollen samples. As a result
the palynological correlations in the published literature have been
tentative and stated with reservations. Despite this the pollen
assemblage stage names have already been used on slender evidence by
other workers.

Some of the present confusion is probably due to an insufficient
understanding of the mass of literature on the Plio-Pleistocene and
Quaternary, and to the fact that the work of early palaeontologists
has never been updated in this country. As a result, most approaches
are still based directly, or indirectly, on the writings of F.W. Harmer
etc. This article is an attempt to update the 'classic' stratigraphic
approach of these writers and thus provide a better comparison with
any other system.

No serious attempt has been made to differentiate between stages,
formations etc., but students of the Crags will have no difficulty in

P. G. Cambridge

recognising and understanding the terms used here. Attempts to form

rigid systems on the Continent have ended in a proliferation of strati-

graphic tables with little agreement. At present there is probably

insufficient basic information but it is hoped that a generally accepted

stratigraphical table of units will eventually be prepared for the whole

area and that the probable temperature fluctuations will be quantified

more closely than the present inferences of "cold" and "temperate"

periods. These tend to be uninformative since both Britain and Canada

have a "temperate" climate at present and there are considerable

obvious differences in their actual temperature limits.

The review which follows is based almost wholly on the marine

macro-fossils, of which the commonest are the molluscs. In this respect

it has the disadvantage of being a largely monophyllatic approach, and

the advantage that the divisions can be easily recognised in the field.

In East Anglia the shelly, marine sands of this period are

referred to as "Crags", which is said to be a local dialect word for

shelly sands. A possible derivation is the word "Craig", which in both

Gaelic and Welsh means a rock. The term Crag is well known in Suffolk

and is often included in place names, such as Crag Farm. An outline of the

Neogene and Hologene stratigraphy of the Southern North Sea, based on the

following discussion, is shown in Table 1.

The East Anglian Crag

The East Anglian Crag may be divided into four series each of which

is dealt with in turn. The lithologies are summarized in Fig. 1.

Coralline Crag (Gedgravian)

The Coralline Crag has a limited exposure in Suffolk, the main mass

of which is an elongate ridge in the Gedgrave-Aldeburgh area, with small

outliers near Sutton, Ramsholt and Tattingstone. An origin as a series

Table 1. The Neogene and Hologene Stratigraphy of the Southern North Sea.

Fig. 1   Summary of the lithology of the Crags in East Anglia.

of off-shore sand-banks has been suggested, but, like the Diestian of

Belgium, it may well prove to have filled a trough in the sea-floor,

with subsequent, preferential erosion of the surrounding material. The

NE-SW alignment of the main axis of the mass is similar to other

troughs containing later Crag deposits at depth.

The Coralline Crag consists of cross-bedded, shallow-water,

calcareous, marine sands, with a very rich fauna. Occasional small

phosphatic nodules occur. At the surface the colour is yellowish-white,

occasionally stained red where in contact with the Red Crag, but at depth

has a greyish-blue colour. The upper part of the series, the Rock Bed

Facies, is partially decalcified and reconsolidated to form a soft,

friable rock in which fossils with calcitic composition, such as pectens,

echinoids and polyzoans are prominent.

Red Crag Series (Waltonian, Newbournian and Butleyan)

Lithologically the whole of the Red Crag series is similar, con-

sisting of shelly, quartzose sands with subordinate clay and silt layers

with redeposited iron oxide. From the base upwards, four types of

sedimentation occur:

1.   Basal Nodule Bed, occupying hollows in the London Clay and con-

taining numerous phosphatic nodules, large irregular flints and a

variety of derivative fossils.

2.   Impersistent, fine quartzose sands, apparently deposited in quiet

water.

3.   Strongly current-bedded sands, representing migrating submarine

dunes, with occasional shell platforms, flaser beds, diapirism and other

structures. Minor nodule beds sometimes occur. Shells are either

scattered through the sands or occur as definite shell seams, often

with one species predominating.

4.   More or less horizontally bedded shelly sands passing up into

decalcified sands.

The typical reddish colour is due to oxidisation of iron and, at

depths, these sands are also a greyish-blue colour. The contained fossils

show that there was considerable reworking of earlier beds throughout

the period of the Red Crag.

Norwich Crag Series

A more variable series of shelly sands, clays and pebbles. The

Chillesford Beds, resting on typical Upper Red Crag at Chillesford, and

on Coralline Crag at Aldeburgh, are considered part of this series,

although the lowest beds, the Scrobicularia Crag, are completely atypical

of the Norwich Crag both in fauna and in the fact that it consists

largely of reworked Red and Coralline Crag.

Shallow water facies of the Norwich Crag, such as the Westleton

Beds, consist almost wholly of well-packed rounded flint pebbles, similar

to those of a beach. In the cliffs between Covehithe and Southwold,

the Baventian Clay is usually included with the marine series, although

macrofossils are generally absent. Above the Baventian Clay on the coast,

in the upper part of the series in the Yare Valley, and elsewhere, are

very varied deposits of sand, gravel, ferruginous clays, flaser beds

etc., which are generally unfossiliferous although sometimes, as at

Caistor St. Edmunds, the sands may show traces of marine boring organisms.

Where seen, the base of the series is usually a layer of eroded, fairly

angular flints, known as the Stone Bed.

The Cromer Series

Due to rapid lateral changes in the lithology and the continuous

coastal erosion of the present day, the stratigraphy of the Cromer Series
is very difficult to follow. Typically, as at Runton, the Stone Bed,
resting on the Chalk, is followed by shelly, ferruginous, marine sands
(the Weybourne Crag), which in turn is overlain by a very variable
series of estuarine and freshwater beds. To the west of Sheringham,
recent (1976) exposures showed a pebble bed with white quartzites,
resting directly on the flint Stone Bed. Within about 200 metres, the
succession changed to green clays and flaser beds, then to an intraforma-
tional breccia of ferruginous clay, and finally to sands and gravels.
Most of the sections, and some of the beds (such as the Yoldia myalis
Bed) of early writers, can no longer be recognised due to erosion. The
fauna of the marine beds of the Weybourne Crag, closely resembles that
of the Norwich Crag.

The Cromer Series are followed by an arctic plant bed of the over-
lying Glacial Series.

The Belgian Plio-Pleistocene

As the series in the Netherlands is known only from borings, the
succession around Antwerp is chosen for comparison. In the last twenty
years there have been numerous temporary exposures in the building of
roads, tunnels and docks and in the Metro workings under Antwerp
itself. The Antwerp Neogene consists of a series of greyish blue,
shelly marine sands. Glauconite is very abundant in the lower part,
imparting a darker colour, hence the early name of the Black Crag of
Antwerp. The amount of glauconite decreases upwards, giving a lighter
colour, and there is an increase in the silt and clay content. In the
pper part of the succession there are distinct shell bands. Owing to the
similarity of lithology throughout, some of the series can only be

distinguished palaeontologically.

Sands of Antwerp (Anversian)

The dark-coloured, Miocene Sands of Antwerp rest on the Oligocene

Clays of Boom. At the top, the junction with the next series is usually

marked by a bed of bored concretions, fossil wood, whale bones etc.

Sands of Kattendijk (Kattendijkian)

Similar dark-coloured sands but with a distinct fauna, now considered

to be Pliocene. Occasional layers of whale bones occur and there are

rare, scattered flint pebbles.

Sands of Luchtbal (Scaldesian)

The lowest member of the Scaldesian. In the dock area this was

frequently seen as a thin, often impersistent shell bed (Falun du

Luchtbal), light in colour, with small pyritic cubes on some of the

shells, or cementing shell fragments. It rests on an eroded surface

of the Kattendijk Sands and many of the shells are worn. Polyzoans

are abundant. On the other side of the river, in the Kallo area, the

Luchtbal is missing but numerous shells, derived from it, occur in the

lower part of the Kallo Sands.

Sands of Kallo (Scaldesian)

Can easily be distinguished from the Kattendijk Sands in the field

by its lighter colour. There are two prominent shell bands (le and 2e

Coquillier). Where the Luchtbal is missing the lower of these shell

bands contains derived shells and rests on a channelled surface of the

Kattendijk. Several faunistic horizons are recognised, including the

Horizon à Pinna, a layer rich in complete shells of this large bivalve,

persistent over a large area.

Sands of Kruisschans

Shelly sands separated from the Kallo only on palaeontological grounds.

Sands of Merksem (Merksemian)

Shelly sands, often with an appearance of reworking, and a light brown colour probably due to oxidisation of the iron since this is the highest part of the succession.

Owing to the high water table, the deposits around Antwerp are permanently saturated and there is therefore less oxidisation and weathering than in the English Crag series. The deposits were laid down in fairly shallow sea but there are no signs of littoral deposits in the Antwerp area. Elsewhere in Belgium other sands occur, probably of the same age, but they are frequently unfossiliferous or decalcified with only moulds and casts (i.e. the Poederlian=Merksemian).

Overlying the main sands of Antwerp is a thin Holocene cover of polder clay, peat (showing peat cutting) and blown sands.

It should be remembered that Belgium is bilingual and that place names may be either in French or Flemish, and horizons etc. may have originally been described in either language. Some anglicisation has been used in this paper.

Subsurface deposits in East Anglia

Almost all early literature refers to shallow exposures of littoral and sublittoral facies or occasional well logs. A number of deep bores have been made to investigate the Crag in recent years and the results published. Obviously the information from borehole samples is limited. For instance it is unlikely that an area of three or four inches diameter will yield a really representative sample of the molluscs on a sea floor. Deposits of the Red Crag series were found in

the lowest part of the Stradbroke borehole but no earlier deposits.

At depth the colour of the Crags is generally a greyish blue, al-
though samples of Norwich Crag, from below Yarmouth, contain many shell
fragments and barnacle valves of a reddish colour. The fragments are
too small for positive identification and it is not possible to say
whether the colour is due to partial oxidisation of more or less
contemporaneous material or whether this may be derived Red Crag material.
Due to facies differences, and the smallness of the samples, correlation
of borehole material with surface exposure faunas is difficult.

The state of preservation in the boreholes is much more favourable
to the survival of microfloras and various pollen assemblages have been
described as biozones. These have not yet been adequately correlated
with outcrop exposures, where pollen is generally poorly preserved, and
no intercalated terrestrial deposits occur. The only really representative
flora and fauna is in the non-marine Upper Freshwater Bed (Cromerian)
of the Cromer Series, but this is younger than any of the marine Crags.

Correlations

The lower parts of the East Anglian and Continental Crags are similar
and some correlations are obvious. Owing to a lack of recent literature
much outdated material appears in English publications. As examples,
a recent paper refers the St. Erth Beds to the "Boytonian" and in another
paper the Lenham Beds are stated to be of the same age as the Coralline
Crag.

Miocene

English textbooks frequently state that the Miocene Formation is
not represented in Britain. In fact at least two Miocene faunas are
known but require description. At Lenham, ironstones in fissures in the

Chalk yielded a suite of molluscan casts which were originally compared

with the Diestian of Belgium, believed at that time to be Pliocene in

age. Since then the Diestian has been shown to belong to the top of

the Upper Miocene. Some of the molluscs, especially the bivalves, have

a long range in time, some being still represented in the Recent fauna,

and this fact must be borne in mind. At Lenham, one of the most charac-

teristic fossils is the bivalve <u>Anadara</u> <u>diluvii</u> (Lamk) found throughout

the Upper Miocene of Belgium, but the genus does not range further than

the Miocene in the North Sea area.

The other Miocene fauna is found in the Boxstones - rounded pebbles

of derived, dark brown, sandstone, found in the Basal Nodule Bed of the

Red Crag. There are collections from the Boxstones in many museums but

the species are commonly misnamed and the fauna requires description.

Species so far named, in the author's collection, include:

Sinodia polytropa (Anderson)   Ficula condita (Brong)

Panopaea menardi Deshayes   Carcharodon megalodon Ag

Glycymeris sp   Laevicardium

<u>Kattendijkian</u>

There seems no evidence that the Lower Pliocene was ever represented

as a marine deposit in East Anglia. No derivative fossils have been

noted from the Coralline Crag, and typical Kattendijk fossils, such as

<u>Astarte</u> <u>corbuloides</u> Lajonk are unknown.

<u>Coralline Crag/Luchtbal</u>

There is an almost complete agreement between the two faunas, both

in species and in general composition. Polyzoans are abundant.

<u>Pseudamusium</u> <u>gerardi</u> is the most typical fossil. There has been a

tendency in England to equate the Coralline Crag with Pliocene but

comparison with the Antwerp beds shows it represents only the lower part of the Upper Pliocene. After deposition the Coralline Crag was exposed to subaerial weathering and decalcification of the upper part, and, during Red Crag times, to marine erosion, since pieces of Coralline Rock Bed are not uncommon in the Red Crag.

"Boytonian"/Kallo

Early in the history of Crag research it was realised that there was a hiatus between the Coralline and Red Crag and F.W. Harmer assumed that a bridging fauna must exist between the two, somewhere. Such a fauna was found by A. Bell, in phosphate workings on the Boyton Marshes, near Butley, containing a mixture of Red and Coralline Crag forms. In his stratigraphic tables Harmer named this the "Boytonian". Subsequently he noted that the material was actually a physical admixture of thin seams of Red and Coralline Crag from below the water level and the name "Boytonian" was dropped from his later tables.

The Red Crag contains a great deal of derived material which could have come from the destruction of Coralline Crag deposits. However, some of these species which appear to be derivative are unknown in the Coralline Crag. In fact beds of Kallo age could have supplied such species as Angulus benedeni,Pecten westendorpianus and others and were probably present in East Anglia and reworked by the Red Crag seas. The numerous Pliocene species of Astarte and Cyclocardia found in the Red Crag could have come from either the Coralline Crag or the missing "Kallo", as they are common to both, and therefore the original extent of the Coralline Crag need not have been so great. From the condition of the derived Kallo material it must have existed in a shelly sand.

Lower_Red_Crag_(Waltonian)/Merksemsian

Once again there is a strong correspondence between the faunas.

Lentidum complanatum is characteristic of both deposits.

Basal_nodule_bed,_Red_Crag

A similar suite of derived material probably occurs under both

Lower and Upper Red Crag. The main sources are the London Clay and

the Miocene, though it is unlikely that the phosphatic nodules all

came from the London Clay as has been suggested. Phosphatised

nodules, with a burrow described as Tasselia ordami de Neinzelin,

occur and this burrow is known only in situ in the Sands of Kruisschans

and the Sands of Merksem. Spiral nodules, originally the core of a

burrow, Gyrohelix, also occur although their original horizon is not

known. Neither Tasselia nor Gyrohelix are recorded from the London

Clay so that some of the phosphatisation must have occurred in Neogene

times.

Cetacean remains, vertebrae, teeth, earbones, fragments of ziphoid

skulls etc., are common and may be Miocene or early Pliocene. The

terrestrial mammalian fauna is rare and very fragmentary. Apart from

a few Eocene specimens the majority are Upper Pliocene, probably

derived from valley deposits during a marine transgression.

In the literature the Basal Nodule Bed is also stated to lie

under the Coralline Crag, with a similar fauna. The original source

of this idea seems to be in a description of a pit at Sutton Knoll,

in Suffolk, which Prestwich described as being worked for phosphate

(or "coprolite" as it was then known). For several reasons I believe

this to be a mistake. At Sutton Knoll the Red Crag surrounds a small

island of Coralline Crag and in the intimate association of the two

deposits the error may lie. Some of the Red Crag pits in the area contain

a proportion of Coralline Crag boulders and slipped material. The site

of the pit, as shown on the sketch map, was on the Rock Bed and would

have meant digging through a considerable thickness of hard beds.

This would have been completely against the normal practice when working

the nodules, which was to locate an outcrop on a valley side and follow

the bed inwards until the cost of removing the overburden became

prohibitive. One of the fields next to the knoll is still known as

the Coprolite Field and shows numerous nodules from the base of the

Red Crag and would have been the obvious place to work the deposit.

Just across the valley, at Ramsholt cliff, the Coralline Crag may be

seen resting on the London Clay with no sign of a nodule bed between,

nor has one been recorded anywhere else where the bottom of the Coralline

Crag has been reached. If such a nodule bed existed it seems strange

that no derived material occurs in the Coralline Crag itself as it

often does in the bulk of the Red Crag. Small, rounded isolated

phosphatic nodules do occur in the Coralline Crag but never seem to

contain any derivative fossils. Until proved otherwise it seems best

to consider the Basal Nodule Bed a part of the Red Crag only.

Upper Red Crag (Newbournian and Butleyan)

There appears to be no Continental equivalent to the Upper Red

Crag whose fauna differs considerably from the Lower. It is difficult

to separate the two 'zones', Newbournian and Butleyan, proposed by

F.W. Harmer. If a stage name is required then the term Orwellian is

proposed, after the river of that name, characterised by 'Cardium'

angustatum and the presence of boreal species in greater abundance.

Chillesford Beds

The Scrobicularia Crag is considered by the present author to be
the lowest member of the Norwich Crag Series, due to the presence of
'Cardium' angustatum and other typical Red Crag forms. It is difficult
to separate the derivative material from the real fauna in these beds.
The reworking of the earlier Crags, the extreme shallowness of the water,
and a general reduction in the size and thickness of the molluscan
shells point to radical changes.

The overlying Chillesford Crag consists of silty beds with some
bivalves in the position of life (Mya) and others with the valves
still joined. The fauna is typical of the Norwich Crag although the
facies is not.

Norwich Crag Series

Harmer included all beds between the Red Crag and the Arctic
Plant Bed in his Icenian stage. Marine and non-marine beds of this
age are known in the Netherlands although an exact correlation with
East Anglia cannot be made at present. Acila cobboldiae, Ptchopotamides
icenicum and other typical Icenian fossils are found in the estuaries
and on the beaches of Zeeland. Among the non-marine molluscs, Viviparus
glacialis found in deposits of unknown age in the Bure valley, is wide-
spread in the Tiglian of the Netherlands.

The Norwich Crag fauna is fairly similar throughout its range,
although there are local variations as would be expected. Many of the
species first appeared in the Upper Red Crag, though some, such as
Hemirhynchia psittacea and Turritealla communis are rare in the Red
Crag. In many of the sections, the upper part contains the freshwater
snail Viviparus medius together with the remains of fish, voles and

other small mammals <u>Macoma</u> <u>calcarea</u> is usually common. This association

is widespread, being found at Thorpe Aldringham, Covehithe Warren,

Bramerton and even in the Weybourne Crag at Weybourne.

In the outcrops, the Norwich Crag is rich in littoral forms such

as <u>Mytilus</u> <u>edulis</u>,<u>Nucella</u> <u>lapillus</u>,<u>Littorina</u> <u>littorea</u> and <u>Hydrobia</u>.

Monstrous forms of some of the gastropods are found in the upper part

of the deposit in the Yare Valley.

Among the more unusual fossils are fish bones showing hyperosteosis

or excessive swelling. These were referred to <u>Platax</u> <u>woodwardi</u> Ag.,

but can be shown to belong to more than one species. The swollen cleithra

have been known from Zeeland for some time and have been found recently

in situ in the Sands of Merksem at Antwerp and there is an example from

the Red Crag in the Ipswich Museum (R.Markham, personal comm.). Thus

the cleithra have a different time range to the remaining '<u>Platax</u>' bones.

Some of these have a strong resemblance to the Eastern American jack-

fish, <u>Carynx</u> <u>hippos</u> from Florida, and may belong to the same family.

A single, elongate vertebra of the 'jackfish' type was picked up on

the beach at Domburg, Zeeland where other Icenian fossils are washed

up but the "butterfly bones" are only recorded from East Anglia. They

are unlikely to belong to <u>Platax</u> which is a tropical Indo-Pacific

genus.

The Norwich Crag was sometimes called the Fluvio-Marine Crag and

non-marine shells are not uncommon. The bivalve <u>Corbicula</u> <u>fluviatilis</u>

occurs at several sites between Aldringham and Wangford, is apparently

missing in the Yare Valley, but is in the author's collection from a

well at Skeyton and from the Weybourne Crag. Both land and freshwater

forms are found with the marine fauna of the Norwich Crag, and perhaps

these, with the vole remains, may be accounted for by the sea occupying

a series of drowned valleys or sheltered inlets, during the early part

of the Norwich Crag transgression. The non-marine fauna is in need of

revision, and especially of comparison with the Continental Tiglian.

The name Mammaliferous Crag was also given to the Norwich Crag

and a large number of vertebrate remains are listed although many of

these are known only from fragments, and indeterminate bone fragments

greatly outnumber determinable material. Remains of marine animals

are generally better preserved and the author has recently collected

vertebrae of dolphins and a large seal, in pits in the Yare Valley.

The larger terrestrial mammal remains are generally very fragmentary

and the fragments are generally sharp and unrolled, even when occurring

in pebbly deposits. It is probable that most of these mammal bones

were already fossilised before incorporation in the marine deposits.

Cromer Series

Typical Weybourne Crag is limited in extent on the North Norfolk

coast but occurs in a very disturbed condition at Weybourne,

under the modern beach deposits at Runton, and on glacially moved Chalk

rafts at Overstrand etc. The fauna is essentially similar to the

Norwich Crag including 'Platax', vole remains, Viviparus medius and

Corbicula fluminalis but is distinguished by the addition of abundant

Macoma balthica. The latter species is characteristic of large

estuaries the sheltered inlets at the present day and prefers a muddy

sand.

Elsewhere on the coast, where there is no overlying Weybourne

Crag, the Stone Bed often contains little but broken examples of Mya

and Arctica islandica. The estuarine sands of the series sometimes contain

marine shells. Thus sands on one of the Chalk rafts at Overstrand

contained large numbers of valves of Mytilus edulis. Layers of flat hard-

ened mud pebbles occur, weathering a reddish-brown, and may be picked up

on the beach in large numbers. These contain shell fragments including

Cardium, fragments of freshwater shells, plant remains and an example

of the polyzoan Flustra foliacea, an assemblage typical of an estuary.

Inland the status of the marine beds of the Cromer Series is

not clear. In the Bure Valley early memoirs record sands and pebble

beds, the upper of which contained Macoma balthica and the lower did

not, but the pits are now all overgrown and require re-excavation. As

mentioned, a well at Skeyton recently yielded a small fauna which

included M.balthica, Corbicula fluminalis,Boreoscala greenlandicum,

Littorina littorea,Cardium edule,Mya arenaria and Arctica islandica.

Marine Temperatures

In the North Sea there was a general cooling from the tropical

deposits of the Eocene to the cold of the Glacial series. The Plio-

Pleistocene deposits of Iceland record between six and eight glacial

cycles large enough to have caused sea-level changes, before the

Anglian. It has been suggested that the large, unworn flints, resting

on the London Clay, below the Red Crag, were ice transported to their

present position ten miles from the Chalk outcrop. The records of

igneous erratics and striated flints found in the Red Crag have never

been backed by photographs, or specimens, and may have been accident-

ally introduced into the Red Crag pits. The most positive evidence

for pre-Anglian cold periods are the ice wedges in sands in the Cromer

Series.

No purely cold water molluscan assemblages are known from the East
Anglian Crags. Harmer believed there was a progressive cooling through-
out the Red Crag period, culminating in the Butleyan and based on an
increasing number of boreal species. However, 'southern' species such
as Calyptraea chinensis are found in the same deposits. In fact marine
temperatures may not follow terrestrial conditions and may be influenced
more by water currents. The upwellings of cold water on the Californian
coast are an example of this sort of control and the warming effects
of the Gulf Stream on Iceland another. The apparent paradox of "hot"
and "cold" species occurring together might be explained by influxes
of northern Pacific genera which are known to have occurred, allowing a
southward expansion of "cold" species. Many of the genera originated as
Pacific boreal forms and entered the North Atlantic and North Sea when
there was free access between the two oceans. It would imply no land
bridge in the Bering Sea and a warmer Arctic Ocean and it can therefore
be argued that boreal forms can actually indicate a warmer climate.

Such influxes occurred in the Miocene, Upper Pliocene and Lower
Pleistocene. The genera Neptunea,Nucella and Panomya, among others
appear in the Kallo for the first time. By the start of the Upper
Red Crag period many Pliocene forms died out and were replaced by
new boreal forms, such as Astarte montagui,Acila,Anomalosipho etc.

Land molluscs in the Crags do not indicate low temperatures.
Helicigona lapicida from the Butleyan would indicate a temperature
no colder than the southern half of Britain; Corbicula fluminalis
which is found in the Norwich and Weybourne Crags is generally
considered a good indicator of warm conditions, being associated with
Hippopotamus in the Interglacials, and at present living in the Nile.

Recently the author has discovered shells of a slug, <u>Parmacella</u>, a
Mediterranean species, in the lower part of the Norwich Crag at Bramerton
and F.W. Harmer figured an example of <u>Otala</u> <u>lactea</u> from the Red Crag.

If this view is correct then the land molluscs indicate warm or
temperate conditions. Rising temperatures which allowed passage
through the arctic seas for molluscs would also cause a general rise in
sea level and therefore local transgressions. The periods of maximum
transgression, such as the Upper Red Crag and the Norwich Crag could
represent maxima of temperature. Conversely, minima would result in
lowering sea level and regression such as occurred in the Upper Pliocene
when the Coralline Crag was exposed to weathering, or during the
shallowing and reworking that occurred during the deposition of the
<u>Scrobicularia</u> Crag. This hypothesis is based on there being no large
scale tectonic movements in the area. The apparent occurrence of small
deposits of Red Crag at Netley Heath etc. up to 600 feet above sea
level needs further investigation. It is not certain whether the iron-
stone was transported to its present position. The determination of
molluscan casts is always difficult and there is the possibility that
like the Lenham Beds these are pre-Crag in age. Thus the Sylter Crag
of Germany, identified as Waltonian from the molluscan casts, was
shown to be Upper Miocene in age.

<u>Extent of the Crags</u>

Fig. 2 shows a diagrammatic indication of the extent of the
various Crags in East Anglia. Harmer suggested a progressively northern
infilling of a Series of bays during the Red Crag, and that no two of
his "zones" were seen in conjunction. The upper Red Crag as a whole,
is higher than the Lower, reaching the present 150 ft contour at Sudbury,

Figure 2.   Distribution of the crags.

P. G. Cambridge

Hascott Hill etc. The extent of the Waltonian may be somewhat greater than Harmer surmised. There have been persistent reports in the old literature of beds similar to the Waltonian occurring in the base of pits in the Newbourne area. A study of material from Boyton Marshes shows a mixture of forms from the Coralline Crag, from the Butleyan and, quite unexpectedly, typical Waltonian fossils. Unless these were mixed by the collector, which seems unlikely, there may be traces of Waltonian in several places, and that the Waltonian beds, being topographically lower, have been mainly destroyed by modern erosion. The transgression associated with the Norwich Crag series also reaches the present 150 foot contour.

For those who live in the low levels of Norfolk there is the not very comforting thought that eventually, if the North Sea continues its present destructive erosive efforts, it may reach its highest Crag levels again with the valleys of the Yare and the Bure becoming drowned estuaries like those near Ipswich.

SEDIMENTS FROM HOLKHAM BEACH, NORTH NORFOLK COAST

W.I. ORONSAYE*

Introduction

The variety of agents at work on the Norfolk coast (such as waves,
tides and wind) and its constant changes in response to erosion and
accretion have made it an excellent area for those interested in
studying coastal processes. Because of similarities in the processes
along this stretch of the coast (from Cromer to Hunstanton), many workers
have found it more convenient to group the whole area as a unit when
studying the morphology and historical development of the entire Norfolk
coast. This may be one of the reasons why there is a very limited
amount of information specifically on such areas as Holkham Bay.

Apart from the works of Steers (1938, 1960, 1961, 1971) and the
brief mention of Holkham Beach in the works of Purchas (1965) and
Clayton (1975), it is surprising how little information is available
on the geology of such a vital area of this coast. The present paper
has grown out of a research project that I have been carrying out in
Holkham Bay since 1974.

Brief Description of Area of Study

Holkham Beach is situated on the North Norfolk coast between
Burnham Overy Staithe and Wells-next-the-Sea. Like the entire North
Norfolk coastline, the above section is orientated East-West. The North
Sea lies due North of the shore line and no other land intervenes

* Department of Geology, Sedgwick Museum, CAMBRIDGE CB2 3EQ

between the study area and the North Pole. The beach is approximately

3000 m long, and reaches a maximum width of about 1,500 m at low spring

tide. The landward side of the beach is edged by a series of dune ridges

known locally as the "Holkham meals". These dunes extend eastwards in

an arcuate form as far as Wells and in an unbroken line westwards to the

eastern side of Burnham harbour. (See Figs. 1 and 2).

Hydrodynamic processes affecting the morphology of the beach

Waves and longshore currents are the main sources of hydraulic

energy on the shores of Holkham Bay. Marked changes in beach profiles

indicate that the sediments are moved extensively by wave action and the

frequently occurring sandbars and runnels around this area are evidences

of longshore currents. (Fig. 2 & Plate 1) Waves with periods up to 15

seconds were recorded in the Bay. Waves of longer periods are generated

in the open sea and their propagation into the Bay is controlled by

the angle of approach and the bottom topography of the area. Summer

storms are uncommon, while storms are common and waves are strongest in

winter. Maximum wave energy is generated in the winter by waves whose

periods range between 8 seconds and 12 seconds. Waves in Holkham Bay

are generated by onshore winds and are only modified by the local winds.

Thus swell of considerable amplitude and energy may occur in this area

in the absence of local winds. The prevailing wind which is from West

to East does not affect the littoral movement, but the dominant winds

which are from the N.E. have much more powerful influence on th e

movements of pebbles and the general movement of longshore drift.

Tides within the study area are semidiurnal. Reconnaissance

studies reveal that the beach sand level is shifted not only by the

daily change of tide, which shifts the zone of breakers away from and
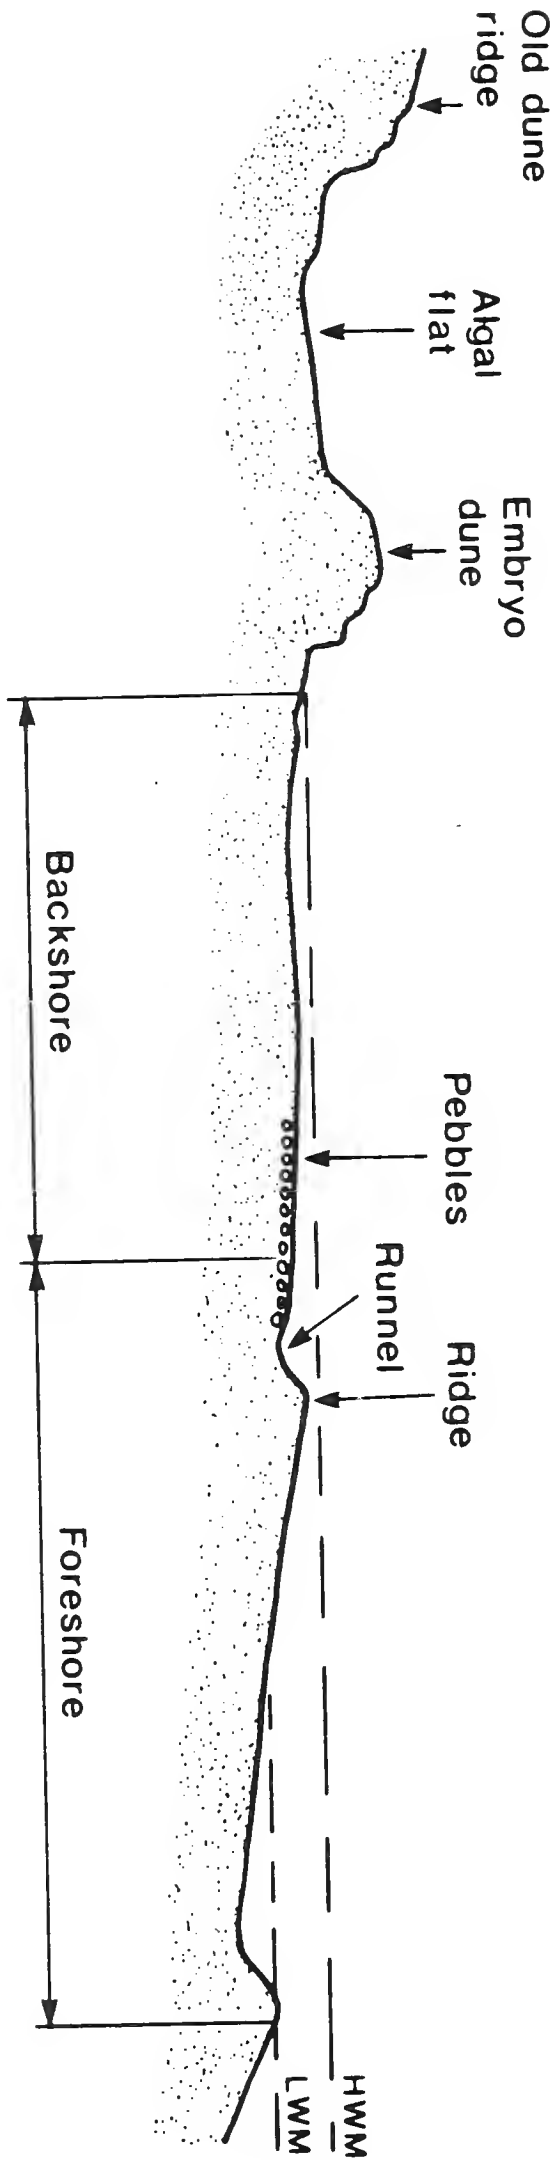

Figure 1.   Holkham Beach Profile (not to scale).

towards the shore, but is affected more markedly by the change from Spring to Neap and from Neap to Spring tides.

Sediments and sedimentary structures

(a) Gravel Beach: As there is no source in the area from which the shingle on this beach could have been derived, it follows that all the pebbles found on the beach must have been transported here by waves or tidal currents from the sea or from other distant beaches. According to Steers (1954) it is evident that most of the shingle and gravel deposits on the North Sea coast have been derived from the vast quantities of stones scattered in boulder clays during the ice-age, which at present covers the floor of the North Sea.

It is obvious from experiments carried out on pebble movements on the beach, and from reconnaissance studies, that waves and not tidal currents are responsible for shingle movement along the beach. The gravel beach rises topographically above and rides laterally over the beach face towards the high water level, and is only reached by Spring tides. Thus it seems unlikely that ordinary wave energy ever attains a sufficient intensity to affect it, except during exceptionally heavy storms.

(b) Sand Beach: Holkham beach possesses a convex beach slope and a uniform distribution of fine grained sand over its upper as well as its lower parts. This configuration has resulted from continuous addition of fine grained sand to the beach by progressive shorewards migration of sand ridges. This process has also, with time, completely buried a once existing back beach gravel accumulation under the sand.

The intertidal sediments in Holkham Bay are medium to fine grained
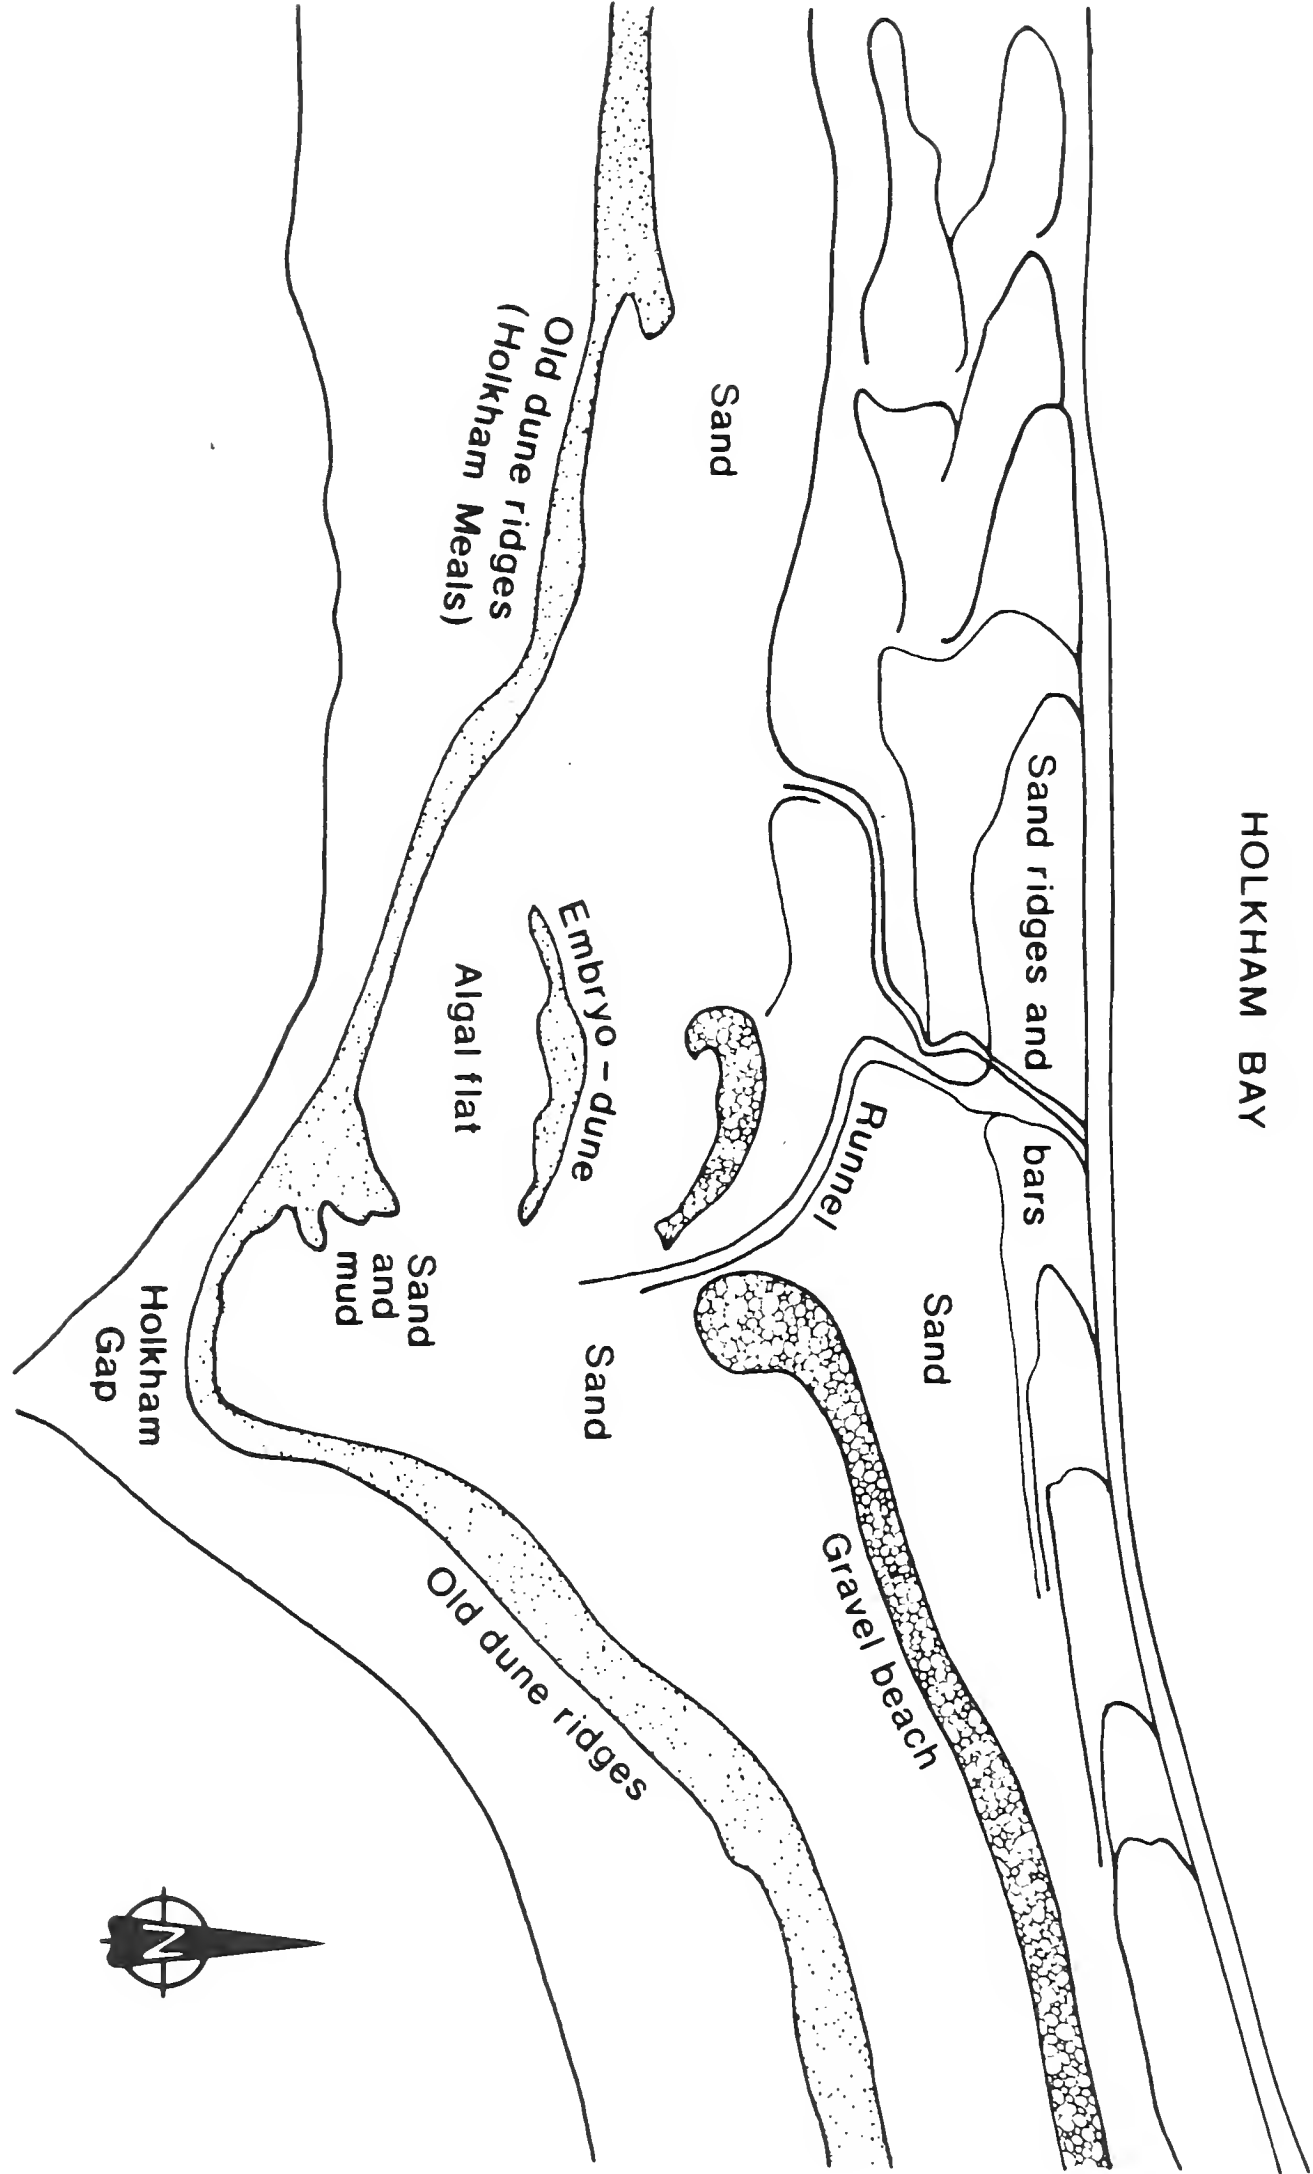

Figure 2.   Sediments of Holkham Beach.

Plate 1.   Aerial photographs of Holkham Beach taken by the Cambridge
           University Aerial Photography Department, 9th January 1975.

sands, mostly well sorted. The sediments occurring at the landward

end of the beach, are less well sorted than those towards the strand

line, and are to a large degree the result of wind action, which winnows

and separates the finer grades from the coarser materials and subsequently

concentrates them in the dunes and on tops of the berm. The mean size

of the sediments range from 0.87∅ to 2.04∅. Skewness value for all the

beach samples range from -0.65 to -0.06.

Table No. 1

Parameters Mean Values	Backshore zone	Foreshore zone	Dune
Mean size MZ∅	2.0	1.92	2.08
Standard Deviation 0,∅	0.35	0.40	0.25
Skewness SK_I	-0.30	-0.25	0.17

The wide variation in the mean size distribution of sediments from

the beach face is related to the wide energy spectrum of the depositing

agency leading to the deposition of coarse, medium and fine sand.

Primary sedimentary structures are plentiful in the intertidal

flat in Holkham; they include erosional structures (scours, crescent

scour, rills and sand shadows) transport and depositional structures

(current and wave ripple marks, interference ripples, streaming and

parting lineations, and runnels) and some post-depositional structures

(sand burrowers, raindrop impressions, textured surface, and foam

impressions). These are frequently occurring during the low tide

period when the beach face is largely exposed.

(c) Algal Flat: The algal flat occurs in the upper part of the intertidal

flat behind what is locally known as the "embryo-dune" in Holkham.

The flat is composed of muds and silts. Surface muds are dark brown.

With depth, the mud becomes blue-grey owing to organic reduction of

iron oxides to sulphides. Deposition of these muds and silt occurs

at high slack water from suspended sediments settling out behind the

"embryo-dune". During periods of low tides and especially during the

Neap tide period, onshore winds blow and deposit sand inland and on top

of the previously deposited layers of mud. This has resulted in

alternate layers of sand and mud in the algal flat. The occurrence of

many typical salt marsh plants just west of Holkham gap is partly due

to these mud deposits and partly because there was once a drainage creek

from the now reclaimed marshes through the Holkham gap. There is a

growing belief that this algal flat is at the early stage of marsh

growth, because the morphology of the area favours the growth of a salt
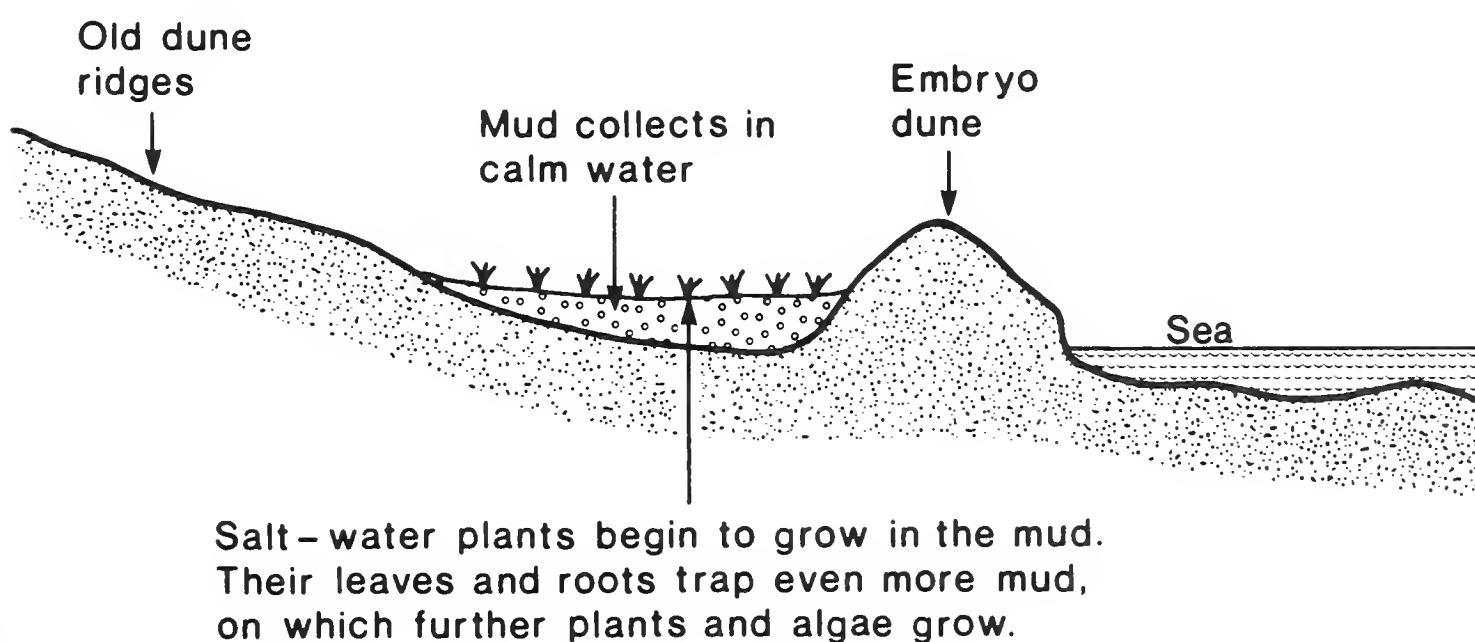

marsh (see Fig. 3).

Fig. 3 Salt-marsh growth.

Conclusion

The description of the sediments has shown that three topographical features - gravel beach, sand beach, and algal flat - can be distinguished in this beach. The sediments at the landward end of the beach are less well sorted than those around the low tide part of the beach. This is because less time is available for wave action to thoroughly rework these sediments as the water retreats during the ebb tide and also, more importantly, due to the extensive winnowing of the sediments by the wind here. On the other hand, the sediments in the lower parts of the beach are better sorted because of the prolonged wave action which removes the finer materials and deposits them in the sea, while at the same time moving the coarser particles further inland as a result of the swash and backwash activity in this zone.

In addition, this work also suggests that the dunes around Holkham Bay have developed as a result of the accumulation of dried out beach sand blown from the open beach, and that this eolian process has been made possible here mainly due to the grain sizes of the sediments in the sand beach. Finally, the accessibility of the beach and the proliferation of sedimentary structures and bedforms of many types along this beach make this area a very suitable natural laboratory for the study of these structures and other coastal processes.

ON THE OCCURRENCE OF Colus ventricosus (Gray, 1839), A PROSOBRANCH MOLLUSC

T. PAIN *

This moderate deep water Colus is today confined to the east coast of North America, from the Grand Banks off Newfoundland to the Georges Bank off Massachusetts.

The shell is very inflated for a Colus, of almost five whorls, with wide, rather faint spiral cords; the aperture is large and slightly longer than the spire. Average length 55 mm. A somewhat thicker more elongated form also occurs, which Harmer (1916, 369) considered a distinct species and which he described as Neptunea tenuistriata. There is however no doubt that this is nothing more than a not uncommon variation of typical C. ventricosus and found living with it. For figures see R.T. Abbott (1974, 209, text fig. 2285) and Harmer (1916, pl. 37, fig. 1).

There is in the S.V. Wood collection in Norwich Museum a shell from the Red Crag of Felixstowe, which Harmer considered to represent Colus ventricosus (Gray), and which he figured (Harmer 1914, pl. 23, fig. 20). Through the kindness of Mr. P. Lawrence, Mr. P. Cambridge and myself have been able to examine this shell, and carefully compare it with recent examples of C. ventricosus from the Grand Banks. There is in our opinion no doubt whatever that it is a small specimen, length 32 mm and somewhat worn, of typical C. ventricosus, and that Harmer's identification is correct.

* 47 Reynolds House, Millbank, LONDON SW1P 4HP

Three other Pleistocene specimens have been referred to <u>C</u>. <u>ventrico-</u>
<u>sus</u>. One, very imperfect, found by Harmer at Oakley, the identification
of which must remain in doubt. Another from the Red Crag of Hollesley is
figured by Harmer (1920, 521, pl. 46, fig. 13) and is said to be in his
collection. This shell is in very poor condition, the base of the
siphonal canal is apprently broken off and the surface is too worn to
show any sculpture, if ever present. Its identification must remain
unproven, in spite of Harmer's statement to the contrary.

The third specimen is from the Pleistocene of Bridlington, Yorks.
This shell is figured by Wood (1872, 22, pl. 3, fig. 4). It is somewhat
damaged, but characteristically inflated and has well preserved spiral
cords and a large aperture. It can reasonably be considered an immature
specimen of <u>C</u>. <u>ventricosus</u>.

The occurrence of this North American species in the British
Pleistocene furnishes evidence of some connection between the two
faunas, as pointed out by Harmer. However the common <u>Colus</u> of eastern
North America, <u>C</u>. <u>stimpsoni</u> (Mörch, 1867) has not so far been recorded
here.

It would seem bery probable that further examples of <u>C</u>. <u>ventricosus</u>
may already be present although unrecognized in collections, or be
collected in the future. It is hoped this note may persuade those concern-
ed to keep a look out for it.

There were five lecture meetings held during the year, one less than normal due to some last minute alterations and difficulties in getting a replacement lecture in the autumn. The meetings were: January, Dr. P.F. Wilkes, 'Some Engineering Problems Related to the Geology of Norfolk'; February, Mr. J. Eiriksson, 'Aspects of Icelandic Geology'; March, Dr. M. Leeder, 'Palaeogeographic and Economic Significance of Devonian and Jurassic River Deposits'; November, Dr. I.N. McCave, 'Deep Sea Drilling in the North-Western Atlantic : Experiences of Glomar Challenger'; December, The Annual General Meeting followed by a showing of the BP film 'Sea Area Forties' and some members' slides. All meetings were held at the University Library.

There were three Committee Meetings during the year.

I am sorry to report that due to increasing domestic and other commitments Mr. Richard Joby has found it necessary to resign from the position of Editor. Mr. Joby has been the Editor since 1971 and has been largely responsible for maintaining the standard of the Bulletin, which is generally acknowledged to be high particularly when taking into consideration the relatively small size of the Society. Grateful thanks are due to him for the not inconsiderable time and effort that he has put into the task of Editorship over the years.

As a whole the Society seems to be in a reasonably healthy state. Membership continues to grow, and even though meetings have been held at the University, with the inconvenience of transport which this causes some members, attendance at lectures has been maintained at a good level.

Once again I would like to point out that the Society exists for the benefit of its members, and I should be grateful for comments and suggestions on any aspect of Society business. The Committee meets during the year to plan ahead and, in order to maintain the Society's healthy state, it is essential that we should be aware of the feelings of the membership. Please feel free to contact any of the Committee and pass on your ideas.

This year's Committee is as follows:

Secretary	Dr. C.J. Aslin
Treasurer	Mr. P.G. Cambridge
Editor	Dr. P.N. Chroston
Field Meeting Secretary	Mr. P.J. Lawrence
Committee Members	Mr. N.E. Dean
	Mrs. E. Evans
	Mr. N.B. Peake

December 1976   Christopher J. Aslin

CONTENTS

The Geological Society of Norfolk exists to promote the study and knowledge of geology, particularly in East Anglia, and holds monthly meetings throughout the year.

Visitors are welcome to attend the meetings and may apply for membership of the Society. For further details write to the Secretary: Dr. C.J. Aslin, the University Library, University of East Anglia, Norwich NR4 7TJ.

Copies of this Bulletin may be obtained, £1 (plus 20p postage), from the Secretary at the address given above; it is issued free to members.

The illustration on the front cover is from Figure 80 (page 468) of the second edition of H.B. Woodward's "The Geology of England and Wales", published by G. Philip & Son, London in 1887. It is after a photograph of a Chalk pit at Whitlingham, near Norwich. The beds above the Chalk with flints, seen best to the right of the picture, comprise 4.5 to 6 m of Norwich Crag Series, made up from bottom to top of: Stone bed; False-bedded sand and gravel, with shells; Impersistent laminate clay, and shelly seam; and Pebbly gravel and sand, with seam of shells.

BULLETIN OF THE
# GEOLOGICAL SOCIETY OF NORFOLK

No. 30   1978

CONTENTS INCLUDE:

EDITORIAL

The Bulletin of the Geological Society of Norfolk seeks to provide
an opportunity for the publication of research papers, notes, or general
articles which are relevant to the geology of Norfolk in particular, or
to East Anglian geology in general. The Society is also prepared to
consider articles of general geological interest for publication, but
normally they will be expected to include some local relevance. There
are no restrictions on subject matter (apart from regional significance)
and indeed a brief look at past issues will show that topics included
range from environmental geology to section descriptions, from geo-
physics to palaeontology and from the Precambrian to Recent. Similarly
there is no formal restriction on length and we welcome full length
research papers, short notes, and correspondence. All papers are norm-
ally refereed.

Potential contributors should note that we prefer manuscripts to
be submitted in typewritten copy, though legible handwriting is accept-
able. In either case, it would be helpful if the style of the paper in
terms of capitalization, underlining, punctuation etc., would conform
strictly to those used in the Bulletin. The reference list is the
author's responsibility alone and should be checked carefully.

Illustrations should be executed in thin dense black ink line.
Thick lines, close stipple or patches of black should be avoided as

these tend to spread in the printing process employed. Original illus-
trations should, before reproduction, fit into an area of 225 mm by 175
mm. Full use should be made of the second (horizontal) dimension which
corresponds to the width of print on the page, but the first (vertical)
dimension is an upper limit only. Reproduction of photographs is norm-
ally possible provided there is adequate contrast.

All measurements in the script and illustrations should be in
metric units.

Bulletin no. 31 will be published in Summer 1979 and contributions
should be sent to me as soon as possible. I am happy to answer any
queries concerning the suitability of a paper or any other editorial
problem.

P.N.C.

THE PLEISTOCENE HISTORY OF WEST NORFOLK

Presidential address given at King's Lynn 21st Feb. 1977.

R.W. GALLOIS*

Abstract

The stratigraphical relationships of the various Pleistocene deposits of West Norfolk are discussed and the field evidence which enables part of the Pleistocene history of the area to be deduced is described. Three cold periods, represented by the Chalky - Jurassic till, the Lower Tottenhill Gravel and the Hunstanton till, can be recognized. These were separated by temperate periods during which the Nar Valley Beds and the Hunstanton raised beach were deposited. Comparison of the West Norfolk sequence with those of the adjacent areas of southern Fenland and Lincolnshire suggests that the Pleistocene history of the area may be more complex than has been previously supposed and that the Pleistocene deposits exposed around the edge of Fenland at the present day provide only a fragmentary record of the history of the period.

Introduction

West Norfolk is a critical area for the study of Pleistocene stratigraphy since it exposes well developed deposits of at least two glacial (the Chalky-Jurassic till and the Hunstanton till) and two temperate episodes (the Nar Valley Beds and the Hunstanton raised beach). The author's knowledge of the area stems from the IGS geological activity in West Norfolk which, in the past ten years, has included

*   Institute of Geological Sciences, London SW7

    Published by permission of the Director, IGS.

field surveys for the preparation of the King's Lynn/Wash (Sheet 129/
145), Wisbech (Sheet 159) and Ely (Sheet 173) 1 to 50 000 scale geol-
ogical maps and site investigations for the Wash Water Storage Feasib-
ility Study and a proposed proton accelerator near Thetford.

Norfolk has gained the reputation of being the graveyard of
British geology (or geologists) because of the number of Pleistocene
howlers it has produced. Most of these have resulted from a limited
amount of observational data being stretched over too big an area in an
unruly haste to 'solve' the Pleistocene stratigraphy of East Anglia.
The history of these hasty correlations now extends back over more
than 100 years.

In deference to the high honour of his office the President
proposed to avoid the ranks of the geological corpses and to discuss
only those aspects of the Pleistocene history of West Norfolk that
could be shown to his satisfaction as a field geologist to be strati-
graphically unambiguous. The following account therefore describes
the field evidence, such as juxtaposition of strata, nature of contacts
and the general distribution and lithology of the Pleistocene deposits,
that can be used to deduce the history of the area. It does not
attempt to correlate the West Norfolk sequence with that of the Midlands,
North Germany or the Alps by means of either fauna or flora. Nor does
it refer to the British Standard Stages proposed by the Geological
Society Quaternary Era Sub-Committee (Mitchell et al 1973) since the
establishment of a standard sequence by adding together type sections
which are geographically widely separated defies all the rules of
stratigraphical nomenclature. The unsatisfactory nature of this
sequence of stages is demonstrated by the assignment of the most

widely distributed glacial deposit in Norfolk, the Chalky - Jurassic till or Chalky Boulder Clay, to the Anglian stage (op. cit., Table 2) in the eastern part of Fenland and the same deposit to the Wolstonian Stage (op. cit., Table 3) in the western part.

The sequence of Pleistocene deposits in West Norfolk and their correlation with the adjoining areas of southern Fenland and south east Lincolnshire are shown in Table 1. The evidence on which this sequence is based is discussed below.

Chalky-Jurassic till

The oldest Pleistocene rocks in West Norfolk are the Chalky-Jurassic till (Chalky Boulder Clay of some authors) and associated sand and gravel. These deposits infill a topography cut into the solid deposits and are made up almost entirely of Upper Jurassic and Cretaceous rocks derived from Lincolnshire and Norfolk.

The Chalky-Jurassic till of West Norfolk now occurs as dissected remnants of what may originally have been an almost continuous deposit (Fig. 1). Thick till sequences are confined to deep valleys in the rock-head surface: thin patches of till occur on the interfluves and on some valley sides. In West Norfolk there are places where valley till is continuous with that extending across the interfluves and there is no evidence to suggest that more than one phase of deposition of Chalky-Jurassic till occurred.

The Chalky-Jurassic till is everywhere characteristically composed of slightly sandy clay with fine and medium gravel-sized erratics of chalk (usually more than 90%), flint, Upper Jurassic cementstone and shale, Lower Cretaceous sandstone and ironstone, Red Chalk, Carstone and rare farther-travelled materials. The lowest part of the till is

Table 1   Correlation of the Pleistocene sequences of West Norfolk and adjacent areas

part of the Wash (after Gallois 1978).

commonly rich in locally derived materials. On the Upper Jurassic and Lower Cretaceous outcrops dark grey clayey tills, derived from the Upper Jurassic and containing Jurassic cementstone and Lower Cretaceous erratics, are overlain by paler grey, more calcareous clays rich in chalk and flint erratics. Evans (1975) has suggested that this lithological difference indicates a readvance of an upper (chalky) till ice across a stagnating lower till ice. In many sections however there is no sharp junction between the two till types and it seems likely that the lower till merely represents a basal layer of slow moving ice.

The erratic content of the Chalky-Jurassic till of West Norfolk suggests derivation from the north-west, from the broad Upper Jurassic clay vale lying between the escarpments of the Lincolnshire Limestone and the Chalk. A more westerly source would have included more Triassic and Lower and Middle Jurassic rocks. A more northerly source would have included more flint from the Middle and Upper Chalk and could not have provided the Upper Jurassic clays since these rocks have only a very limited outcrop in the North Sea (see IGS Sub-Pleistocene Geological Map, 1974 for details).

On the eastern edge of Fenland, between Dersingham and Denver, the Lower Cretaceous escarpment is broken by four east-west valleys whose floors and sides are cut in Chalky-Jurassic till (Fig. 2). At present these valleys carry small streams, the Babingley River, the Gaywood River, the Middleton Stop Drain and the River Nar. The extent of the glacial deposits in their floors and sides suggests that these valleys and streams were formerly much larger.

The glacially-filled Babingley valley rises near Great Massingham (TF 780 210) and from there can be traced westwards, via boreholes

that proved thick glacial deposits at Grimston (146/404a)*, Congham
(146/8) and Hillington (145/73a), to the present day Babingley valley
at Castle Rising. West of Castle Rising the valley passes beneath the
Recent sediments of the marshlands and its course is presumed to
continue almost due west via boreholes at Vinegar Middle (TF 6092 2505)
and Ongar Hill (TF 5767 2444) until it meets another glacially-filled
valley in the vicinity of the River Nene.

The glacially-filled Gaywood valley can be traced from Roydon
Common (TF 690 218) southwards and then westwards beneath the valley of
the present day Gaywood River to Gaywood Bridge (TF 638 214). West of
Gaywood Bridge, the course of the glacially-filled valley is hidden by
Recent deposits. There is insufficient borehole data to indicate its
position beneath the northern part of King's Lynn but it probably turns
northwards to become a tributary of the Babingley valley.

The glacially-filled Middleton valley lies beneath the present
valley of the Middleton Stop Drain and is well defined between Fairstead
(TF 645 190) and Middleton Towers Station (TF 670 180). West of Fair-
stead, its course is lost beneath Recent sediments under King's Lynn;
east of Middleton Towers, it rapidly broadens until, at East Winch, it
merges with a broad outcrop of glacial deposits which is connected to
the Nar valley.

In the Cretaceous outcrop area, where it can best be studied, the
glacially-filled Nar valley is the longest and broadest of the valleys
in West Norfolk. The start of the glacially-filled valley is hidden
beneath the thick glacial deposits of the boulder clay plateau in the
area of Litcham (TF 886 177) and it is not known whether or not the

---

* Institute of Geological Sciences Well Catalogue number.

valley is a closed basin. West of Litcham, the course of the valley is well defined by wells at Lexham (146/20) and Castle Acre (146/194 and 146/238), from where it can be traced to Narford (TF 765 140). Westwards from Narford its course beneath extensive spreads of Pleistocene and Recent deposits is uncertain but it probably turns north-westwards at Narborough and then south-westwards at West Bilney and passes beneath the Recent deposits of Fenland near Blackborough End. Boreholes at Wiggenhall St Peter (TF 6030 1319), Lordsbridge (TF 5704 1244), Spice Chase (TF 5513 1292) and West Walton (TF 4913 1316) show its course to continue westwards from Blackborouth End to the Nene.

The positions of other glacially-filled valleys in Fenland are largely conjectural because of the scarcity of boreholes in the area.

The present day River Wissey follows the course of a drift-filled valley that appears to be locally up to 70 m deep between West Tofts and Stoke Ferry. A tributary valley may join the main valley at Stoke Ferry and from there run westwards to join a small glacially-filled valley at Fordham (TL 617 999).

Between Fordham and Littleport site investigation boreholes show that Upper Jurassic clays are everywhere present at shallow depth beneath Fenland. The lower reaches of the rivers Wissey, Little Ouse, Cam and Lark, which cross this area, must therefore be postglacial features. The Cam and Lark both have well documented deep, drift-filled valleys in their upper reaches. It has been suggested that the buried valley of the Cam drained southwards and that of the Lark drained south-eastwards away from Fenland (Woodland 1970, p 540 and Plate 28).

Boreholes at Boston, Crowland, Long Sutton, March, Salters Lode and Wisbech have proved thick drift sequences which may indicate the

positions of valleys associated with a glacially-filled Gt Ouse drainage system. Horton (1970) has traced the drift-filled valley of the River Gt Ouse, which he interpreted as a preglacial valley, from Stony Stratford as far north as Huntingdon. The possible course of the drift-filled valley of the Gt Ouse beneath Fenland must be largely speculative. Drift sequences over 40 m thick have been proved at Wisbech, (site investigation boreholes) Long Sutton (e.g. 145/10 and 11), Fosdyke (144/2) and Boston (128/5).

Seismic profiling carried out within The Wash for the Water Storage Feasibility Study proved the presence of several deep glacially-filled valleys (Wingfield et al. 1978). These valleys, together with those in Fenland, have been interpreted (Gallois 1978) as part of a preglacial river system that was graded to a sea-level about 100 m below that of the present day. This system, which consisted of the Gt Ouse, Nene, Cam, Lark, Wissey, Little Ouse, Welland and part of the Trent, probably drained through a single valley which breached the Chalk escarpment in the central part of the Wash (Fig. 2).

The reasons for interpreting this drainage system as one of fluvial origin, albeit glacially modified, rather than one of wholly subglacial origin can be summarized as follows:-

(1) The glacially-filled valleys show no preferred orientation but appear to form a dendritic pattern draining towards a single outlet in the Wash.

(2) The glacially-filled valleys of the Babingley, Gaywood, Nene and Ouse rivers are closed basins with outlets only into Fenland.

(3) The cross profiles and long profiles of the glacially-filled valleys beneath The Wash can be seen, in the seismic sections, to have

gentle slopes and to show many of the subtleties of form that are associated with fluvial erosion and subaerial weathering.

(4)   The lithology of the infilling material in the valleys is remarkably constant,being Chalky/Jurassic till in the lower parts and water-sorted till and varved clay in the upper parts.

(5)   The contact of the till and the underlying Upper Jurassic clays is almost everywhere gradational and indicative of erosion by ice rather than by subglacial waters. Chalky till commonly passes down into Jurassic clay-rich till that rests on in situ Jurassic clay cut by polished shear surfaces.

In the area adjacent to West Norfolk, Woodland (1970) has interpreted the borehole data from the boulder clay plateau areas of central and east Norfolk as showing tunnel valleys cut in the chalk surface. Cox and Nickless (1972) have used a similar explanation to account for the extensive spreads of glacial sand and gravel in the Norwich area and Sparks and West (1965) considered the buried valley beneath the upper reaches of the River Cam to have resulted from subglacial erosion.

The apparent presence of a preglacial valley system and a tunnel valley system beneath the Chalky-Jurassic till of adjacent parts of Norfolk is not incompatible. Boreholes have proved drift-filled valleys more than 100 m deep in the area just east of the present day Nar-Wensum watershed (Woodland 1970). Such valleys do not appear to extend westwards to breach the Chalk escarpment between Hunstanton and Stoke Ferry, but rise irregularly eastwards towards the position of a former ice front (Cox and Nickless 1972). The present day watershed, between streams flowing westwards to the Ouse drainage and eastwards to the Yare drainage, approximately marks the dividing line between the areas

of presumed preglacial and subglacial drainage (Fig. 2). This line lies
a little to the east of what in preglacial times must have been an'
impressive Chalk escarpment comparable to that of the present day
Chilterns or the North or South Downs. The roots of this escarpment
now occur as a belt of almost drift-free chalk separating the patchily
drift-covered areas of West Norfolk from the completely drift-covered
till plateau of central Norfolk. Debris from this escarpment is
scattered throughout the Chalky-Jurassic till of East Anglia.

The position of the former escarpment is indicated by the presence,
at a number of localities, of exceptionally large erratics within the
Chalky-Jurassic till. These erratics expose parts of the local strati-
graphy but lie several kilometres west of the present day outcrops of
the rocks they contain. It is clear from the till matrix and smaller
erratics that the Chalky-Jurassic till in West Norfolk could only have
been derived from the West or North West. The large erratics are there-
fore likely to lie close to the original position of the escarpment.

At Rising Lodge, King's Lynn (TF 668 230) there are transported
masses of Gault and Chalk which are probably hundreds of metres in
length. At Leziate (TF 677 192) the till encloses an erratic of Car-
stone and Gault about 50 m long; at The Howdale, Downham Market (TF 617
029) there is an erratic of similar size composed of Carstone, Red
Chalk and Gault; finally, at Roslyn Hole, Ely (TL 555 808) Skertchly
(1877) recorded an enormous mass of Kimmeridge Clay, Lower Greensand,
Gault, Cambridge Greensand and Chalk within the Chalky-Jurassic till.

Between the north Norfolk coast and Stoke Ferry the present day
Chalk escarpment, although divided into two parts (a Lower Chalk and an
Upper Chalk escarpment) and much lower than its southern counterpart,

lies within a few kilometres of its presumed preglacial position. It

appears to have been eroded by ice moving from the north-west at an

oblique angle to the escarpment. Between Stoke Ferry and Ely the former

escarpment was eroded by ice rich in Triassic material debris (derived

from the west) which moved onto it at right angles so that the escarp-

ment was eroded back eastwards by over 10 km in places. This has given

rise to the large embayment now occupied by Methwold and Lakenheath

fens. Within this embayment the islands of Hilgay, Southery, Littleport

and Ely probably mark the line of the former escarpment.

To the east of the presumed position of the former Chalk escarpment

the rivers Wissey, Lark and Cam have buried valleys which have been

interpreted as sub-glacial valleys draining south-eastwards or southwards

(Woodland 1970, Plate 1). To the west of the former escarpment the

rivers Babingley, Nar and Gt Ouse appear to have preglacial valleys

infilled by glacial deposits (Fig. 2). The Chalk escarpment seems

therefore to have been a temporary barrier to the ice movement and to

have separated an area of predominant erosion in the west from one of

deposition in the east. The preglacial valleys are interpreted as

scarp-slope valleys that have suffered little glacial modification.

The tunnel valleys may be former dipslope valleys which have undergone

extensive modification.

An interesting problem that arises from this interpretation is the

question of what was happening to the north of the chalk escarpment in

north west Norfolk. If, as is suggested here, the chalk escarpment

decisively influenced the flow of the ice which deposited the Chalky-

Jurassic till, then one might expect to find a contemporaneous till of

differing lithology in the north east Lincolnshire coastal plain and in

Norfolk north of Docking, the most northerly spillover point for the Chalky-Jurassic ice.

The Chalky-Jurassic till in the preglacial valleys of West Norfolk is generally less stony and better sorted in its upper part and, in the case of the valleys of the Babingley River, the Middleton Stop Drain and the River Nar, becomes interbedded with varved clay before finally passing up into varved clay. A gas pipeline trench in the Middleton Stop Drain valley (TF 650 174 to 668 178) showed that varved clay in the central part of the valley passed laterally, via water-sorted almost stoneless till, into heterogeneous Chalky-Jurassic till in the valley side. When traced away from the valley floor towards the inter- fluve the stones in this till became coarser and the till generally more heterogeneous.

Nar Valley Beds

The Nar Valley Beds comprise a lower, freshwater unit, the Nar Valley Freshwater Beds, overlain by a marine unit, the Nar Valley Clay. Their relationship to the varved clay of the glacially-filled valleys is not yet clear but it seems likely that the two deposits are conform- able. Shell-and-auger boreholes drilled by IGS in the Nar valley near Setch (TF 6458 1394 and TF 6377 1435) proved fine-grained grey silty sands and silts (basal part of the Nar Valley Freshwater Beds) resting on grey silts with widely spaced laminae of reddish brown clay (highest part of the varved clay sequence). These latter passed down into varved clay. The varved clay was probably deposited in a series of small ice-dammed lakes during the retreat phase of the glaciation which produced the Chalky-Jurassic till. The Nar Valley Freshwater Beds, from which Stevens (1960) obtained a flora indicative of an ameliorating

climate, may therefore represent the last stages of that glaciation
and the early stages of the subsequent interglacial stage.

The Nar Valley Clay consists of finely laminated marine clays,
silts and silty clays and has been proved at outcrop (Stevens op. cit.)
and in boreholes to overlie the Nar Valley Freshwater Beds. In the
lower part of the Nar Valley the base of this marine clay in the IGS
boreholes at Setch and in Tottenhill Gravel Pit (TF 633 115) is marked
by a shell bed composed almost entirely of large oysters which rests
disconformably on freshwater peat of the Nar Valley Freshwater Beds.
The age of both the peat and the oyster bed have been shown by radiocarbon
dating (samples IGS C14/129 and IGS C14/222) to exceed 46,000 years.
In the central part of the Nar Valley near Setch the junction of the
marine and freshwater sequences is at about 8.5 m below O.D. Traced
towards the valley sides the junction rises to about 4 m above O.D. at
Tottenhill and 2.0 m below O.D. at Setch village. The junction rises
eastwards as it is traced up the valley and is at more than 6 m above
O.D. in the valley side at Horse Fen, West Bilney (TF 692 142) (Stevens
1960, p. 295) and at about 13 m above O.D. at East Winch (TF 705 116)
(Young in Institute of Geological Sciences 1972, p. 23).

The Nar Valley Clay has yielded a rich fauna of bivalves (see
Whitaker et al. 1893, pp. 84-85 for details) which indicate a slightly
brackish marine environment comparable to that of the present day Wash.
The clay was clearly deposited during a period of rising sea level in
a sea which transgressed eastwards across the Nar Valley Freshwater Beds
and older Pleistocene deposits. Exposures of undoubted Nar Valley Clay
have been recorded at heights up to 24 m above O.D. in the Narford area
which suggests a minimum sea level at least 30 m above O.D. at the time

of maximum extent of the transgression if later isostatic or other

differential land movement is assumed to be absent. Sparsely stony

clays mapped as Nar Valley Clay by Whitaker et al. (1893, p. 89) in

the Ashwicken area (TF 698 188) at heights greater than 30 m above O.D.

have been re-interpreted by the present author as water-sorted till.

Stevens concluded (op. cit. pp. 291) that the flora of the Nar

Valley Beds show a climatic optimum to have been reached during the

latter part of the period of deposition of the Nar Valley Freshwater

Beds. This suggests a rapid return to temperate conditions in West

Norfolk after the retreat of the Chalky-Jurassic till ice since the

field evidence indicates a rise in sea level of at least 30 m after

the optimum.

Before considering the events which followed the deposition of

the Nar Valley Clay it is convenient to move to the north Norfolk coast

to examine the field relationships of West Norfolk's other till, the

Hunstanton till.

Hunstanton till

The outcrop of the Hunstanton till is confined largely to low-lying

ground along the north Norfolk coast and the eastern edge of The Wash

between Hunstanton and Wolferton (Fig. 1). It is everywhere thin

(probably less than 10 metres) on the land area in West Norfolk.

Glacial sand and gravel deposits associated with the till extend over

a larger area than the till and include the famous esker at Hunstanton

Park and well developed kames and a possible collapsed esker in the

valley of the Heacham River.

The Hunstanton till is characteristically a dull reddish brown

sandy clay, in which the red colouration is thought to be largely derived

from Triassic marls, containing chalk and flint erratics together with

a large percentage of Bunter pebbles, Carboniferous sandstones and

coals, schistose and gneissic metamorphic rocks and a variety of igneous

rocks. Among the more easily identifiable igneous rocks are Whin Sill

dolerite from northern England and rare rhomb prophyry from Norway.

Despite the emphasis in the literature on the more exotic erratics,

chalk and flint are by far the most common stones in this till in West

Norfolk. Many of the far-travelled erratics can be matched with rocks

which crop out on the east coast of northern England and southern

Scotland and it is clear that the bulk of the Hunstanton till was

deposited by an ice-stream which flowed southward down the western side

of the North Sea.

The relationship of the Chalky-Jurassic till to the Hunstanton

till cannot be directly demonstrated at the present time. There have

been records of reddish brown Hunstanton-type till overlying grey

Chalky-Jurassic-type till, but these need to be interpreted with

caution since the Hunstanton till is locally so rich in Cretaceous

material as to be indistinguishable from the Cretaceous-rich parts of

the Chalky-Jurassic till.

Hunstanton raised beach

At Hunstanton and Old Hunstanton the till overlies well-rounded

chalk and flint gravels which appear to be a former beach deposit

banked against an old cliff cut in Chalk, Red Chalk and Carstone. The

feature made by this former cliff can be traced westwards from Old

Hunstanton to Morston where Solomon (1932) described a similar beach

deposit (the Morston Raised Beach) beneath supposed Hunstanton till.

In 1975 IGS made an excavation in the car park of the Le Strange

Arms Hotel, Old Hunstanton (TF 681425) on the edge of the former cliff
to establish the stratigraphical sequence and, if possible, to obtain
dateable shells from the Pleistocene beach. The following section was
exposed (Fig. 3):

Blown sand; made ground and soil wash: blown sand banked up

against seaward side of degraded artificial bank

..... up to 0.8m

Bed (4)   Hunstanton till: stiff dull reddish brown sparsely

stony clay; stones mostly fine gravel size flints

and chalks with rarer Carstone, Red Chalk, rotted

sandstone (?Carboniferous), granite, rotted coal,

rotted ironstone, vein quartz and unidentified

igneous rocks; irregular, cryoturbated base with

pipes of till extending up to 0.3m into underlying

bed   ..... up to 0.9m

Bed (3)   Cryoturbated chalk gravel: fine and medium gravel

sized angular chalk fragments set in a matrix

of chalk paste and dull reddish brown clay;

larger chalk fragments joint bounded; thoroughly

jumbled mass devoid of bedding or sorting;

irregular passage at base into   ..... up to 0.9m

Bed (2)   Imbricated chalk gravel: sand grade to boulder

sized angular, chalk fragments set in a matrix

of poorly sorted sand and fine and medium gravel;

larger blocks show imbricate structure dipping

north westwards; lenses of fine sand in upper

part of bed become replaced by thin interbeds of

gravel at seaward end of section   ..... 0.3m seen

The lower part of the section, Beds (1) and (2), are similar in struc-

ture and content to parts of the debris cones which occur along

Hunstanton cliffs at the present time. It seems likely that the

excavation was made at a point where the old chalk cliff is indented

and the Pleistocene beach is overlain by chalk scree and sludge.

Former exposures at Hunstanton gasworks (TF 672 402) showed the

beach deposit to contain layers of shelly sand with a fauna of marine

gastropods and bivalves interbedded with well-rounded gravels composed

largely of far-travelled erratics (Whitaker and Jukes-Browne 1889, p.

90). The molluscan fauna, which can be matched with that of the present

day Wash and North Sea, combined with the height of the gravels

(maximum about 8 m above O.D.) suggests they were deposited under a

climate and sea level similar to that of the present day. The problem

then arises of the origin of the glacially-transported erratics in the 'interglacial' beach (see below).

No outcrop of the Hunstanton raised beach has ever been described, since it appears to have everywhere been overridden by the Hunstanton till. However, there are extensive outcrops of gravels, similar to those of the Hunstanton raised beach and lying at a similar height above sea-level. These are the Tottenhill Gravels.

These are the Tottenhill Gravels.   ·

Tottenhill Gravels

Between Hardwick (TF 631 182) and Wimbotsham (TF 608 058) an almost continuous narrow strip of flint gravel forms an eastern limit to the Fenland Holocene deposits. North of Hardwick, beneath the urban areas of Gaywood and South Wootton, patches of similar gravel have been exposed from time to time.

Whitaker et al. (1893, p. 91) interpreted this long strip of gravel as a terrace deposit marking the east bank of a forerunner of the River Gt Ouse. However, there is no evidence that the Gt Ouse, or indeed any other Fenland river, followed a course along the eastern edge of the Fens before its diversion there in Roman times and it is difficult to envisage a river without a western bank. Whitaker (in Whitaker and Jukes-Browne 1889, p. 92) later suggested that similar patches of gravel near King's Lynn might have a marine origin comparable with that of the Hunstanton raised beach. Few exposures have occurred in these gravels in recent years but those that have, at West Winch, Stowbridge and Tottenhill, have provided useful stratigraphical information.

A gas pipeline trench at West Winch (TF 631 167) revealed 3.0 m

of cross-bedded sand and well rounded flint gravel banked against a low

cliff of Chalky-Jurassic till and soliflucted brown sandy till (Fig. 4).

A section on the opposite side of the A10, a few metres to the west,

showed ·3.5 m of sandy, fine-grained, well rounded flint gravel with

cross-bedding dipping gently eastwards. The notch at the base of the

cliff was estimated to be about 4.0 m above O.D.

At Stowbridge (TF 614 074) about 3 m of similar flint gravel rests

on Kimmeridge Clay. The upper surfaces of the gravels at West Winch

(about 7.6 m above O.D.) and Stowbridge (about 6.7 m above O.D.) are

at similar heights. The base of the gravels at West Winch (about 4.0m

above O.D. estimated) and Stowbridge (about 3.7 m above O.D.) are also

at similar levels.

The most informative section described in the Pleistocene rocks

of West Norfolk in recent years has been that in Tottenhill Gravel Pit

(TF 632 116) at the mouth of the Nar Valley. Here, the Nar Valley

Beds can be seen to be unconformably overlain by a complex sequence of

flint gravels (Fig. 5) which have been termed the Tottenhill Gravels

(Gallois 1978). These gravels can be divided into two parts. The

lower part, up to 5 m thick, consists of medium and coarse, poorly

sorted, mostly angular gravels and is characterized by cross-bedding

which dips steeply (20 to 25°) to the south-east and by frost wedge

and cryoturbation structures. The gravels contain numerous pebbles of

woody and reedy peat, soft brown clay, varved clay and Jurassic and

Lower Cretaceous erratics, all presumed to have been derived from

nearby outcrops of Nar Valley Beds and glacial deposits. The upper

gravels (about 3.5 m thick) are fine and medium, are better sorted

than the lower gravels and have planar cross bedding which dips west-

       derived from Nar Valley Beds
       and Chalky-Jurassic till.

Bed 4 Upper Tottenhill Gravel: flint gravel
       with low angle cross bedding; patchy
       calcrete at base: transgressive across
       cryoturbation structures in 3

Bed 5 ? Till: cryotubated mixture of dull
       red-brown, sparsely stony, sandy
       clay and gravelly sand

Bed 6 Gravelly sand: cryotubated and
       irregularly piped into underlying
       bed

wards at 8° to 15°. The junction of the two units is a well defined, slightly uneven surface 5.0 to 5.2 m above O.D., in part calcite-cemented, along which the upper gravels truncate cryoturbation and bedding structures in the lower gravels.
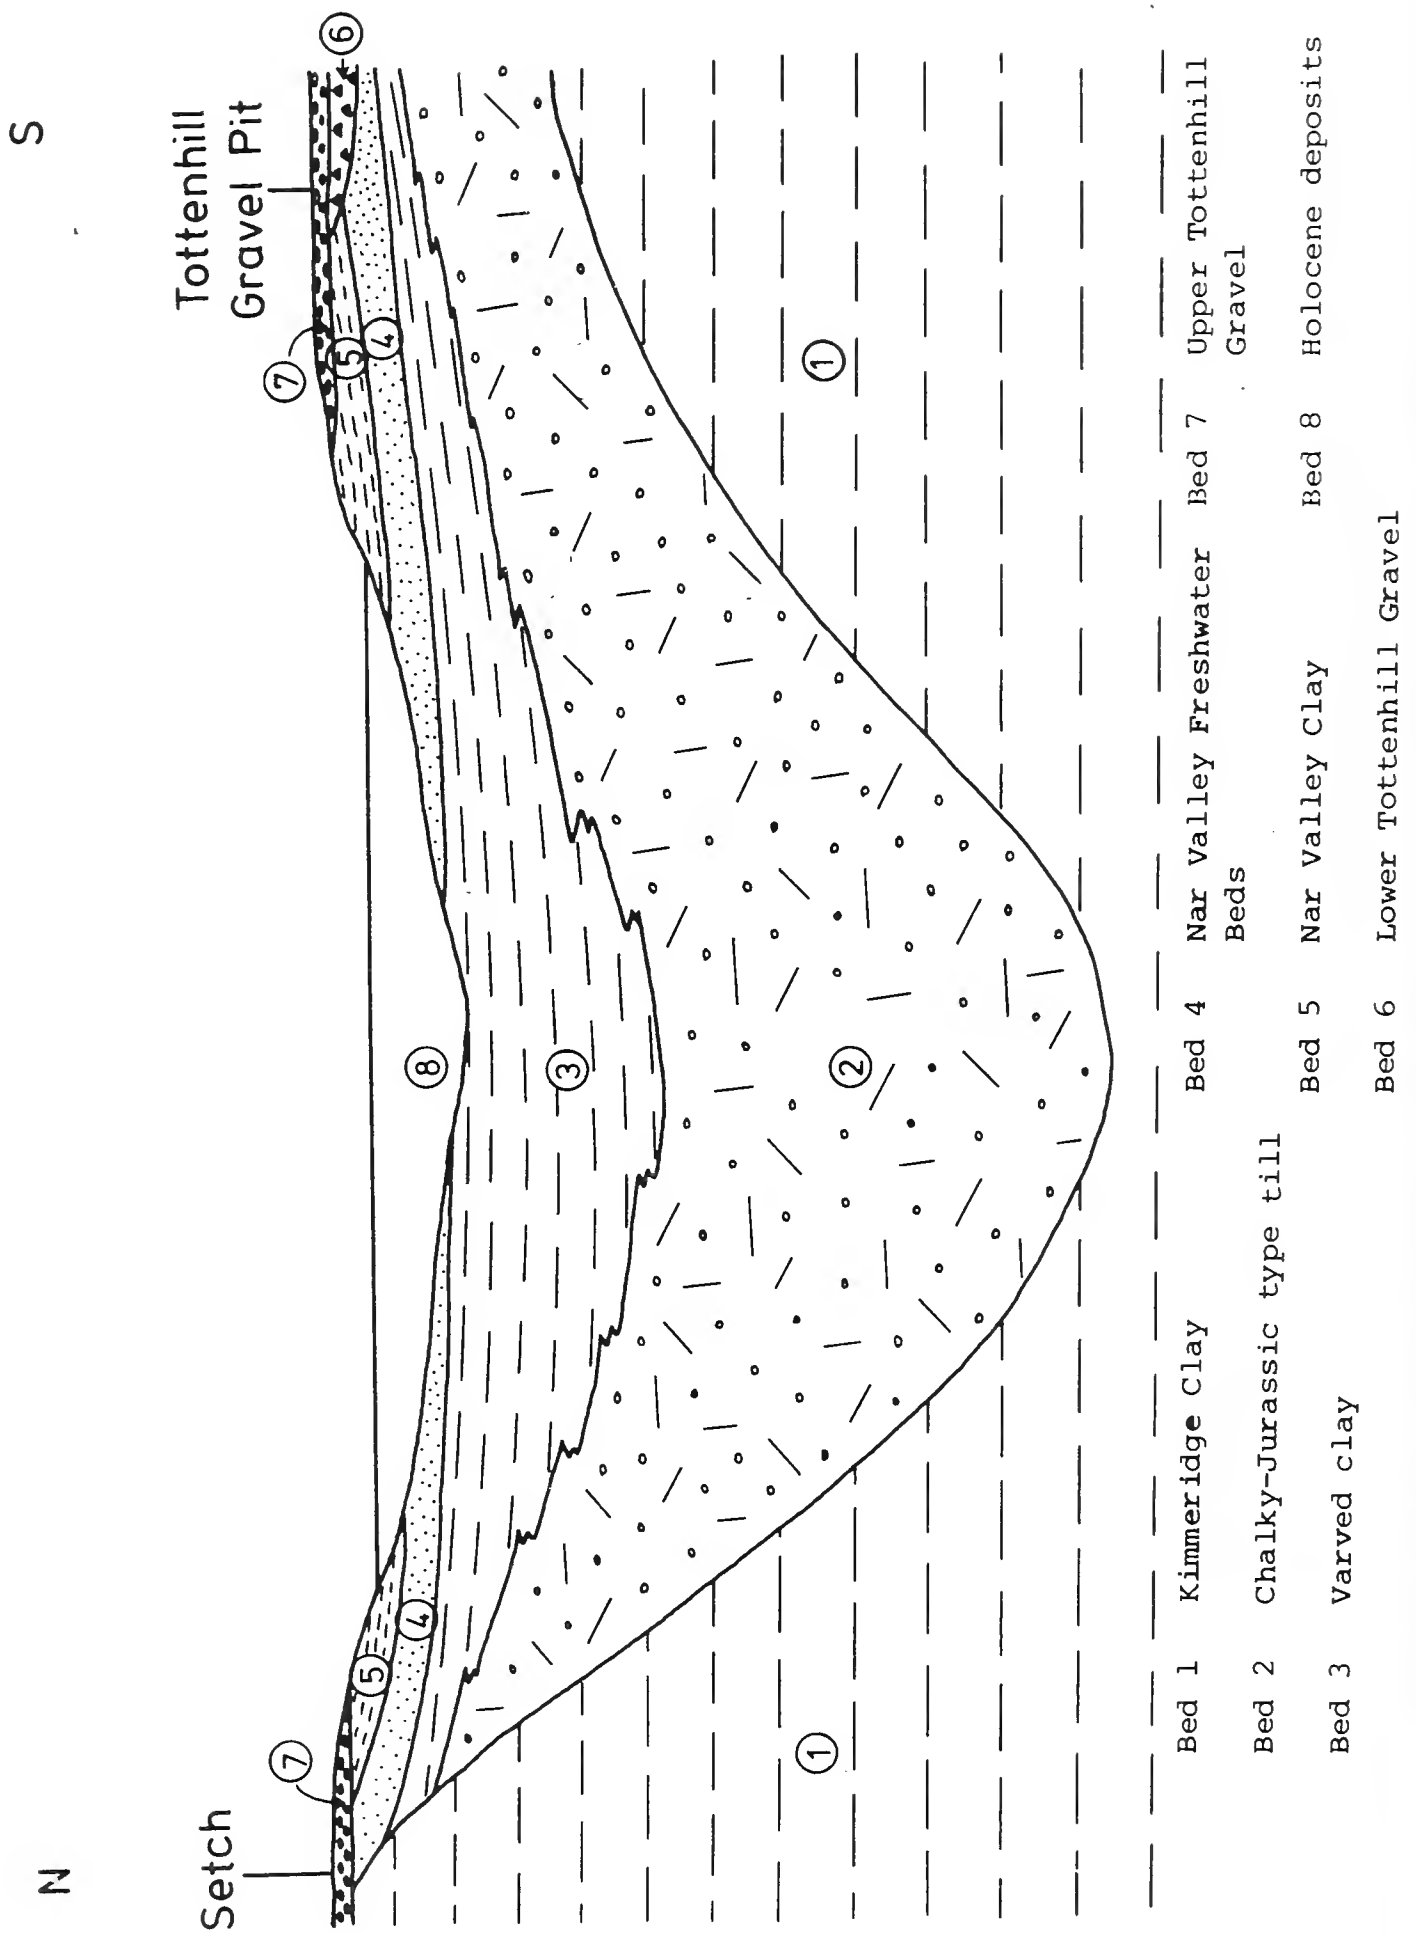

In the south eastern part of the main pit (TF 6330 1135) the upper gravels are overlain by up to 1 metre of cryoturbated dull brown and reddish brown, sparsely stony, sandy clay and clayey sand which passes southwards along the section into dirty clayey sand. This lithology is reminiscent of the more sandy parts of the Hunstanton till, and although the stones are almost enitrely angular flints the clay and the under-lying Upper Tottenhill Gravel also contain possible 'Bunter' quartzites and rare igneous rocks. These last include a distinctive quartz porphyry which was found in the reddish brown clay and is identical with material in the Hunstanton till at Hunstanton. The relationships of the Pleistocene deposits at the mouth of the Nar valley are shown diagram-matically in Fig. 6.

Baden-Powell and West (1960, p. 79) and Stevens (op. cit., p. 295) have described sections at Blackborough End gravel pits (TF 684 145) in which gravels of presumed glacial origin overlay the Nar Valley Beds. Whether these gravels represent the main mass of the Blackborough End Gravels, part of the Tottenhill Gravels or soliflucted material derived from the Blackborough End Gravels is unclear as the sections are no longer visible and were never satisfactorily described.

Correlation with Lincolnshire

Tills of similar lithology to both the Chalky-Jurassic till and the Hunstanton till occur in Lincolnshire and south east Yorkshire.

The Chalky-Jurassic till that infills the valleys beneath Fenland

is lithologically similar to that which extensively outcrops in the Upper Jurassic clay vale of Lincolnshire. This latter is believed to be the oldest till in Lincolnshire and therefore seems likely to be the correlative of the Chalky-Jurassic till of West Norfolk. Much of the coastal plain of south east Yorkshire and east Lincolnshire is underlain by a complex of brown, reddish brown and purple tills which have been correlated with the Hunstanton till on the basis of lithology and landforms. The statement by Shotton et al.(1977, p. 274) that the thickest of the Yorkshire tills, the Drab, "has been traced via the Marsh Till of Lincolnshire into the Hunstanton Till of west Norfolk" is incorrect since the closest Lincolnshire and Norfolk outcrops are more than 30 km apart.

In the Holderness peninsula of Yorkshire Jukes-Browne (1885) described a series of tills (the Purple, Drab and Hessle), lithologically similar in part to the Hunstanton till, that overlie a beach deposit and chalk cliff comparable to that at Hunstanton. At Sewerby, Yorkshire (TA 199 686) Lamplugh (1888) described this beach as composed of shingle rich in far-travelled erratics (the same types as occur in the Hunstanton raised beach) together with a molluscan fauna (which can also be matched with that from Hunstanton) and vertebrate bones. The molluscan fauna is not diagnostic of age but it does suggest a similar climatic regime for both the Sewerby and Hunstanton beaches.

The vertebrates from Sewerby include warm climate forms of the elephant, hippopotamus and rhinoceros (Boylan 1967) and are said to be indicative of an interglacial rather than an interstadial phase (Catt and Penny 1966, p. 386). Catt and Penny (1966, p. 387) have also recorded an older till, the Basement Till, overlain by the raised

beach at Sewerby and it is from this latter till that the far-travelled erratics in the beach deposit are presumed to have been derived. If this interpretation is correct then, by analogy, one might expect to find an older till, lithologically similar to the Hunstanton till, in the offshore area close to the north Norfolk coast.

It has been noted above that the Chalky-Jurassic till appears to be restricted in Fenland and The Wash to the area lying to the south and west of the preglacial chalk escarpment. It is possible therefore that several phases of Hunstanton-lithology till were deposited to the north and east of the escarpment.

Organic freshwater silts at Dimlington, Lincolnshire (TA 391 217), which lie between the Basement and Drab tills, have been radiocarbon dated as about 18,500 years old (Penny et al. 1969). This date supports Straw's (1960) suggestion that the Hunstanton till represents the maximum extent of the last glaciation in East Anglia. This seems likely to be correct but it should be borne in mind that the correlation between the Drab and Hunstanton tills has yet to be conclusively demonstrated. The most convincing evidence for the correlation is circumstantial, the freshness of the Hunstanton till landforms (e.g. the Hunstanton Park esker) and the relationship of the till to the buried cliff and raised beach.

Correlation with southern Fenland

The distribution of the Chalky-Jurassic till and its associated sand and gravel deposits is patchy in southern Fenland but they appear to rest everywhere on solid rocks and to infill a preglacial valley system which is connected to that of West Norfolk. At March, Cambridgeshire the Chalky-Jurassic till is unconformably overlain by a

Pleistocene salt marsh deposit which in turn is overlain by shelly, storm beach gravels, the March Gravels (Gallois 1976, p. 18). These gravels have been tentatively correlated, on the basis of their height above sea-level and their fauna, with the Hunstanton raised beach. At a number of localities Marr and King (1928) and Baden-Powell (1934) recorded 'brickearth', a chocolate coloured stony sandy clay, overlying the March Gravels and thereby providing circumstantial evidence that the Hunstanton raised beach, Upper Tottenhill Gravel and March Gravels may formerly have been a single deposit overlain by the Hunstanton till, Tottenhill ?till and March 'brickearth' respectively.

The lower part of the Tottenhill Gravels, by virtue of their included frost structures and the torrential nature of their deposition, probably indicate a cold phase younger than the Nar Valley Clay. The relationship of these gravels to the gravels at Blackborough End and Wormeagay, both of which are presumed to be of glacial origin and associated with the Chalky-Jurassic till, is unknown. Gravels of this age have not been reported from southern Fenland.

All the rivers that drain into Fenland have flint gravel terrace deposits (usually designated Terrace 1 or Terrace 1-2) at levels close to or a little above O.D. In southern Fenland the rivers Cam, Lark, Gt Ouse, Little Ouse, and Wissey have extensive outcrops of this 'Fen edge gravel'. The field relationship of these gravels to the March Gravels shows the former to be the younger. Radiocarbon dates of organic material within the first terrace of the Gt Ouse at Earith have given an age of 42,000 years B.P. (Bell 1970). Frost structures within the gravels testify to cold conditions at times during their deposition. Their coarseness suggests deposition by torrents of meltwater since

these rivers are capable of carrying only clay grade material during
the present temperate climate.

None of these gravel deposits extends more than a few kilometres
seaward from the edge of Fenland: any downstream parts of the deposits
therefore have either been completely removed by subsequent erosion
(an unlikely explanation in the case of flint gravels such as these)
or were never deposited. This suggests that the gravels were deposited
as fans in a body of water such as a lake. If this latter explanation
is correct then one would expect fine-grained lacustrine sediments to
have been contemporaneously deposited over much of Fenland, but such
deposits have not yet been found. Reconstructions of the limit of the
glaciation that deposited the Hunstanton till (e.g. Suggate and West
1959) envisage the mouth of The Wash blocked by ice. A Fenland glacial
lake would therefore be a likely consequence of this blockage and
would explain the curious feature of the Fenland 'islands' such as
Southery, Hilgay and March which appear to have been formed at some
period before the deposition of the Holocene sediments which now
surround them.

Summary of Pleistocene history

Finally, a word of caution. The main problems that occur in
Pleistocene stratigraphy arise mainly from the laterally variable
nature of glacial and interglacial sediments, from their lack of unique
floras and faunas and from their potentially repetitive nature. This
last point is of particular importance in West Norfolk and needs to be
recognised if errors are not to be perpetuated and compounded. If ice
moved across the area more than once, and if the direction of the ice
movement was the same on each occasion, then one would expect tills of

similar lithology to be produced. There is evidence in West Norfolk

for only one phase of deposition of Chalky-Jurassic till and one of

Hunstanton till. However, these two tills are of different ages. It

can be argued that when the Hunstanton till was being deposited at the

most southerly extent of its ice-sheet, the area to the south, where

the Chalky-Jurassic till crops out, experienced a periglacial climate.

It is difficult however, to envisage a regime in which Chalky-Jurassic

till was deposited in the south without an older Hunstanton-type till

being deposited contemporaneously in the north. Our knowledge of these

glacial events is still very limited.

Even more limited is our knowledge of the various Pleistocene

temperate phases. The position of the Nar Valley Beds in the strati-

graphical sequence seems secure but the record of other temperate

phase deposits around Fenland, such as the Hunstanton raised beach, the

Wretton interglacial deposits (Sparks and West 1970), the March Gravels

and the salt marsh clay underlying them, and the Woodston Beds (Horton

et al. 1972), is fragmentary. It is here that the difficulty of

repetition of environment is likely to be most keenly felt for it is

clear that sea-levels comparable to those of the present day probably

existed on a number of occasions during the Pleistocene. Each maximum

level is likely to have left behind patches of its more resistant

deposits such as storm beaches and these may in some cases, as at

March, have protected underlying less resistant strata. As yet we have

no sure way of distinguishing the ages of these deposits. To make

correlations on the basis of their heights above sea level merely

assumes that they represent the deposits of a single temperate phase.

In the following summary of the Pleistocene history of West Norfolk

the simplest explanation has been devised that fits the field observa-
tions. This simple summary (Fig. 7) will undoubtedly become more
complex as the stratigraphy of the area becomes better understood.

In preglacial times the rivers of West Norfolk drained westwards
from the chalk escarpment to join a major river that ran northwards to
breach the escarpment in the central part of what is now The Wash.
These rivers became graded to a sea-level at about 100 m below O.D.
prior to the onset of glaciation. The ice which deposited the Chalky-
Jurassic till overrode this drainage system and the valleys became
filled first with till and, in the late stages of the glaciation, with
varved clay. Climatic amelioration then led to the deposition of
freshwater gravelly sands and peats (the Nar Valley Freshwater Beds)
which were overstepped by marine clays (the Nar Valley Clay) as sea-
level continued to rise to at least 30 m above O.D. Analyses of peat
and shells from the Nar Valley Beds have shown them to be beyond the
range of radiocarbon dating (i.e.> 46,000 years B.P.).

There then followed a period of erosion of unknown duration during
which large volumes of Chalky-Jurassic till and Nar Valley Beds must
have been removed for the next deposit in West Norfolk consists of
torrent-gravels containing frost structures (the Lower Tottenhill
Gravel). In the absence of positive dating evidence the simplest
assumption as to their age is that they were deposited during an early
phase of the Hunstanton glaciation. No till of this age has been
recognised in Fenland and it is possible that the area was inundated
by a lake formed by ice blocking the mouth of The Wash.

The climate again became warmer and the Hunstanton raised beach
and the Upper Tottenhill Gravel were deposited in a temperate period

when sea-level was slightly higher than today. The last glaciation of West Norfolk was marked by the deposition of the Hunstanton till from ice that may have reached as far south as the Nar Valley at Tottenhill and southern Fenland at March. Finally, periglacial features such as frost polygons and stripes, stone polygons, 'hills and holes' topography, cambering and solifluction were extensively formed during this glaciation and after the last ice sheet had retreated.

The Pleistocene period came to end in West Norfolk when the sea re-invaded the low-lying parts of the area. Deposition of the Holocene deposits then began and the scene was set for the formation of the fascinating complex of sediments that was to become Fenland .... but that is another story.

THE INFLUENCE OF CHALK FRACTURES UPON THE VALLEYS OF NORTH AND WEST NORFOLK

R. TOYNTON*

Introduction

The orientation of fractures within the Chalk of Norfolk have been measured at each of the outcrops located within the county. These outcrops are concentrated in the west of the county, near the northern coast and within the larger river valleys elsewhere. To the east of Norwich the Chalk becomes increasingly obscured by Crag deposits, the most easterly in situ exposure being at Postwick, about 6 km. to the east of the city. The western limit of the Chalk in Norfolk is shown on Figure 1.

Over much of central Norfolk the Chalk is covered by glacial deposits often exceeding 20 metres in thickness. These deposits, which consist in the main of boulder clays, tend to remove any influences of the underlying Chalk upon the present topography. Thus in seeking evidence for the influence of chalk fracture patterns on valley alignments, the five areas used as examples are all in the west and north of Norfolk.

The bedding of the Chalk dips towards the east at approximately 1^{0}. The surface of the Chalk also declines in the same direction from maxima of over 80 metres above sea level in the west of the area considered, around Anmer, Great Massingham and Swaffham, to sea level a few kilometres to the east of Norwich. Further to the east the surface of

* School of Environmental Sciences, University of East Anglia,

   Norwich NR4 7TJ.

the Chalk bevels down more steeply beneath the Crag and the Eocene deposits.

Valleys

Valley features in the Chalk may be divided into four types:-

1. Stream Valleys:

Surface valleys occupied by flowing water are the most common of those considered. Since these valleys are still undergoing modification by fluvial processes it is important to consider the general alignments of the stream valleys rather than the actual courses of the streams themselves. Even in areas with considerable thicknesses of glacial material most stream valleys are formed into the underlying Chalk.

The extreme headwaters of some of the streams flow in shallow depressions on the boulder clay surface and thus cannot be expected to display any particular orientational preferences.

2. Dry Valleys:

Numerous dry valleys occur in the western area of the Chalk outcrop, mostly where not overlain by boulder clay. Formed by fluvial processes at times when the water table has been at higher levels relative to the land surface, these features tend to be less sinuous than the valleys occupied by flowing water at present. Seasonal and longer term fluctuations in the level of the water table may cause some valleys to change from dry to wet on occasion.

3. Buried Valleys:

Though many present valleys may represent a postglacial re-excavation of preglacial features, it is more straightforward to define buried valleys as those preglacial forms which, due to infilling
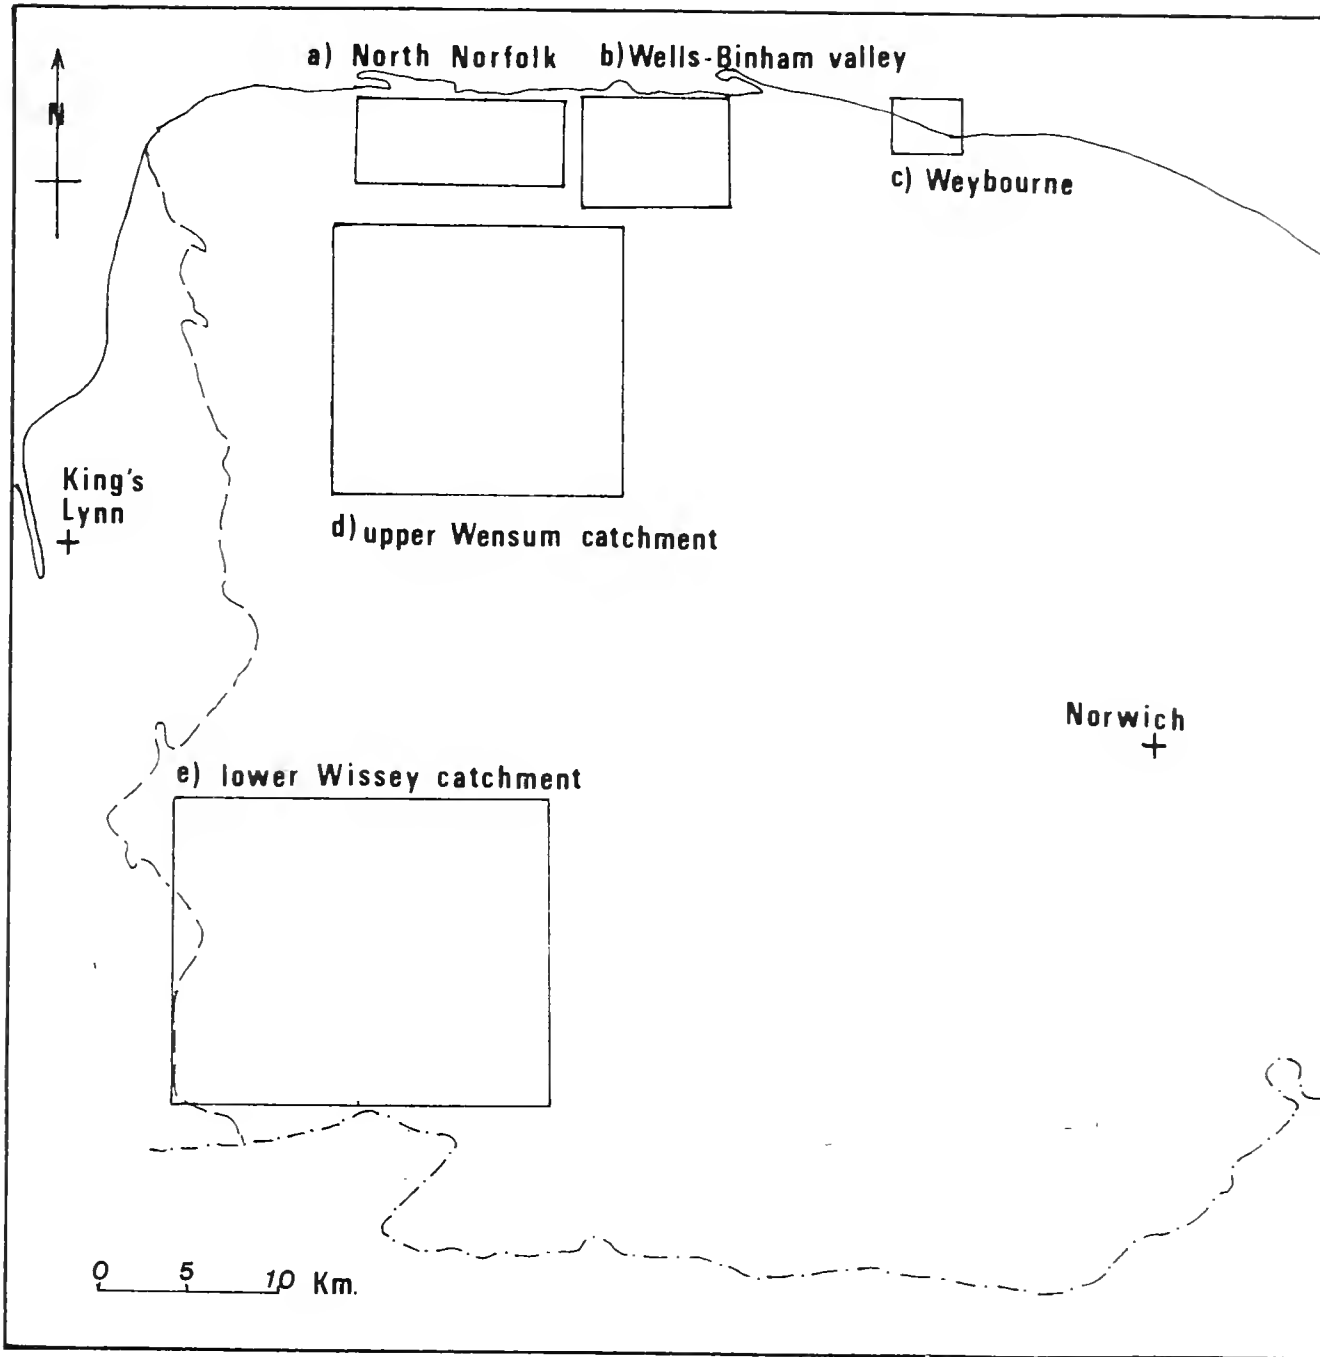

Figure 1.   Location of example areas.

by glacial deposits, no longer have any expression on the land surface.

4.   Buried Channels:

Known also as tunnel-valleys, the buried channels of Norfolk are deep, steep-sided features formed by water flowing under pressure beneath the Pleistocene ice sheet. The buried channels occur throughout most of Norfolk, and also occur commonly elsewhere in East Anglia (Woodland 1969). Near Hingham one such channel exceeds 100 metres in depth. Those in the south of Norfolk tend to be orientated from west to east, cutting across the watershed, whilst elsewhere they often occur beneath present stream valleys.

Being subglacially formed by water under variable pressure, the buried channels may vary considerably in depth from place to place. This lack of any semblance of a graded long profile distinguishes these channels from surface formed valleys. The buried valleys are infilled with glacial and fluvioglacial deposits.

The influence of Chalk fracture orientations upon valley features may involve the inheritance of alignments.

The preglacial valleys would have formed on a chalk surface and thus be directly influenced by that stratum. Similarly the buried channels would have been formed by water following lines of least resistance on the surface of the Chalk. In many cases these would be provided by the preglacial valley depressions in the Chalk surface; in others by the orientation of the dominant fracture set, the influence of which would be exaggerated by the mechanical weathering of the surface of the Chalk under periglacial and glacial conditions. Present surface valleys often follow the courses of buried channels possibly due either to the re-establishment of a preglacial drainage route imposed by the

general topography of the area, or to the preferential erosion of the less resistant infill material.

On Figures 2(a) to 2(e), where types are duplicated along a single alignment, only one feature has been included for the sake of simplicity. This has been done by giving present surface priority over buried features where they coincide.
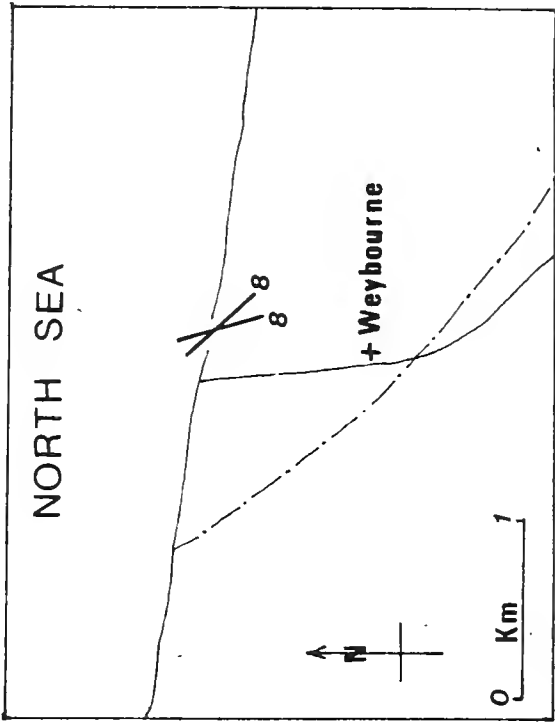

Chalk Fracture Orientations

At every Chalk exposure of sufficient size located in Norfolk, fifty values of the strike and dip of fracture planes have been measured. These measurements have been taken at random points on the exposed face using a compass-clinometer.

Most of the exposures consist of vertical or near vertical faces of Chalk. In this situation it is likely that in addition to the pre-existing fracture sets, the pressure release due to the formation of the exposed face will form another fracture set parallel to this face. However, since most exposures have either more than one Chalk face or one which varies in orientation, by taking measurements at random points the pressure release effect is relegated to a background 'noise' above which the true fracture sets will show up.

No measurements of width of fracture or of absolute frequency of occurrence have been made. Since all of the measurements have been taken from within the basal two metres of each exposure (i.e. the height easily reached while standing on the base), then depending on the height of each exposed section the level being measured will vary in its depth below the original Chalk surface. In most of the exposed sections it is very noticeable that the Chalk face becomes increasingly broken by fractures towards the top, and similarly that the width of

the fractures may vary with depth, whether due to mode of formation or weathering processes. Thus, where the depth of the Chalk exposure below the original surface is not taken into consideration, measurements of the actual frequency and width of fractures are meaningless. The occurrence of certain orientations of fracturing within the fifty readings taken at each site is a measure in terms of relative frequency, and thus comparisons between sites are possible.

In order to determine the main orientations and relative strengths of fracturing, stereographic projections have been used. The use of the stereogram is a method of plotting planes on a circular net representing the surface of a sphere (Phillips 1971).

If the circular stereogram is viewed as one hemisphere, then a vertical plane intersecting this hemisphere appears as a straight line passing through the centre of the diagram. The orientation of this line from the north point represents the orientation of the vertical plane. Similarly a horizontal plane appears as a line around the circumference of the diagram. A plane with an intermediate dip thus appears as an arc, with the distance of the mid-point of the arc from the circumference of the stereogram as a measure of the dip from horizontal, and the points of intersection of the arc with the edges of the stereogram as the orientation of the strike of the plane.

The line normal to a plane (the pole) may be represented by a single point on the surface of the other hemisphere. Thus a point on circumference of the diagram is the pole to the vertical plane, the orientation of which is at 90° to the point. A pole falling at the centre of the diagram represents a horizontal plane, and so on.

Using this method the poles to the fracture planes measured at

each Chalk exposure have been plotted on separate stereograms. By considering the percentage of the poles which fall within each 1% of the area of the stereogram, concentrations of poles may be identified, contoured and compared.

Figure 3 shows two contrasting stereogram contour plots. That of measurements at Grimes Graves shows three distinct fracture sets. Two of these have dips which are on average near vertical, while the third, weaker set is in general horizontal. The orientations of the strikes of the near vertical fracture sets are marked outside the circumference of the stereogram with the additional number being that of the concentration in terms of percentage poles per 1% area.

The stereogram of the fracture poles at Marham shows in contrast no marked concentrations of near vertical fractures, the only distinct set being one dipping at about 10° to the north-west.

If a random set of dips and strikes were to be plotted on a stereogram the result should be a concentration of one over the total area. On the maps of Figures 2(a) to 2(e) only those orientations with concentration values of 8 or over are shown except where those of 6 are of special relevance to the regional pattern. On these maps, single lines at the relevant orientations are employed rather than the complete stereograms for the sake of simplicity.

Fracture Orientation and Valley Alignment

Figures 2(a) to 2(e) are largely self-explanatory, though a few additional notes may help draw attention to the important features.

a)   North Norfolk

At each of the five Chalk exposures within this area a concentration of fracture orientations at about 090° exists. Over much of the
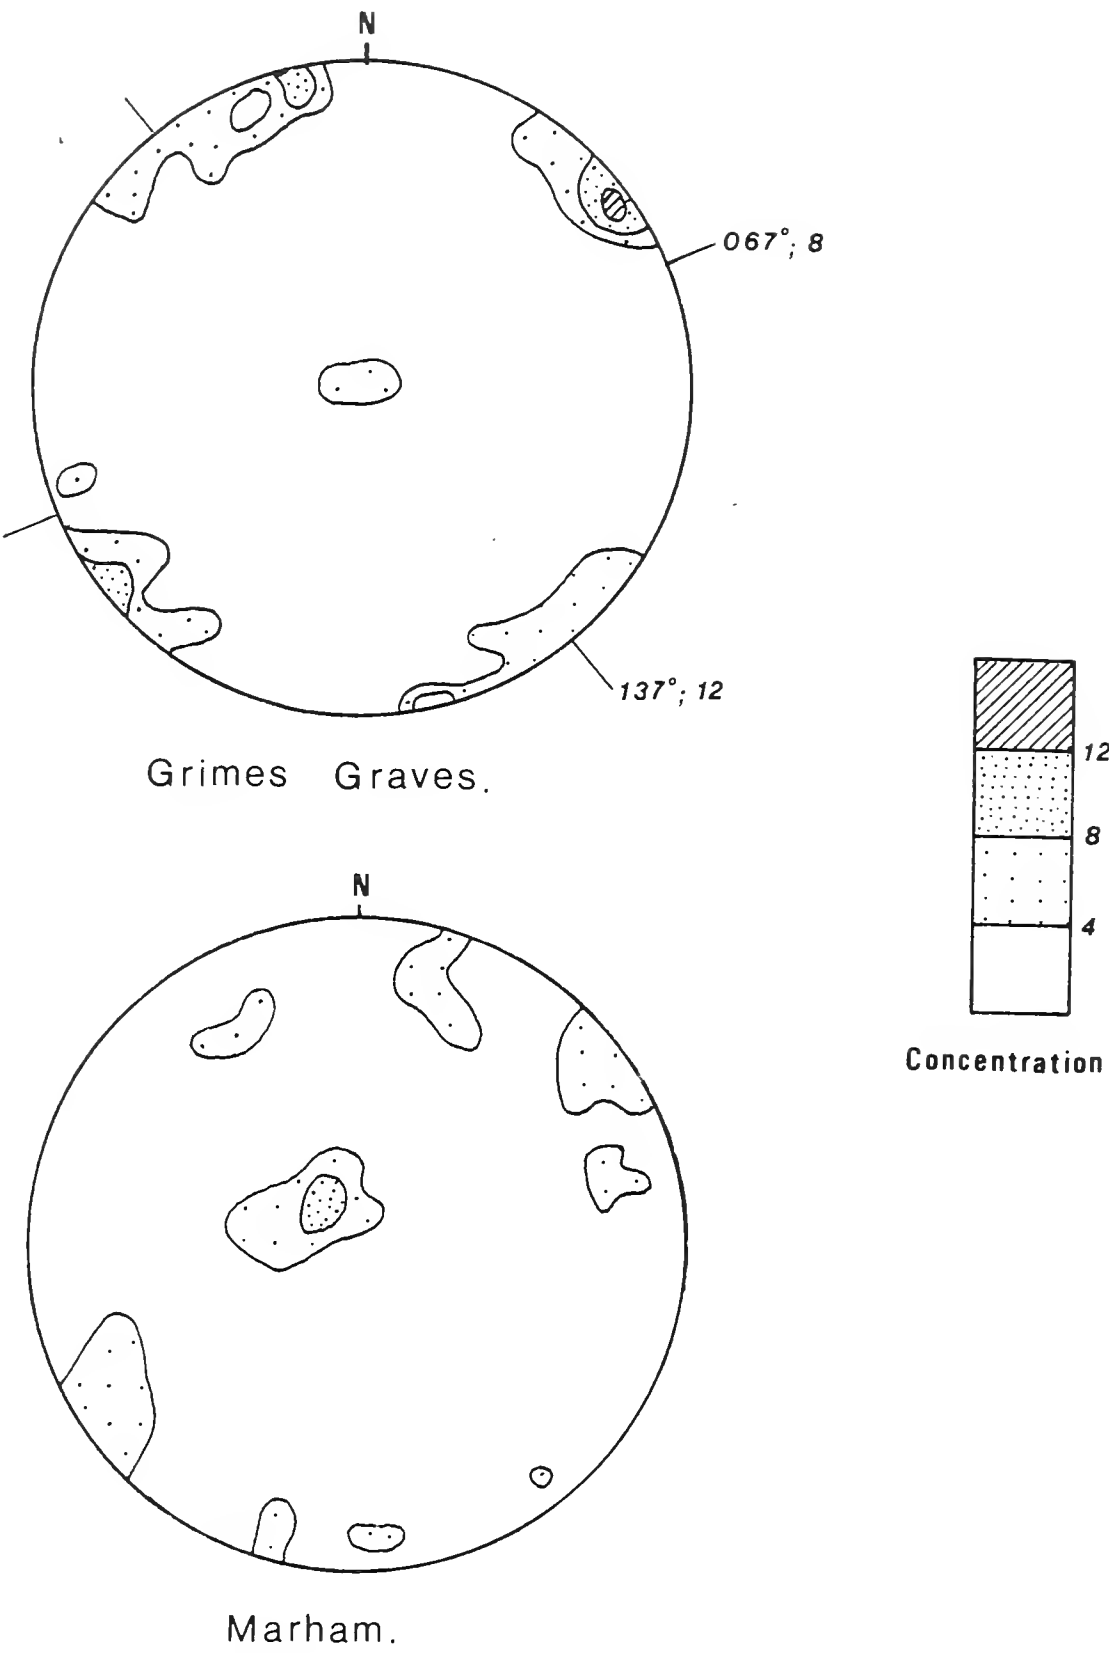

Grimes   Graves.

Marham.

Concentration

Figure 3   Typical   stereograph plots of contoured poles to
            fracture planes.

rest of Norfolk orientations of around 050^0 to 060^0 and 130^0 to 140^0 are most common, and thus the north coast area is unusual. Noticeably close to the 090^0 orientation is the Chalk slope just inland from the coast, parallel to which is a shallow dry valley extending from Wells in the east to Burnham Overy in the west. A buried valley coincides with this dry valley. The east-west orientation of fractures in the Chalk close to the north coast of Norfolk may well be associated with faulting believed to exist with this same orientation in the basement rocks below the Chalk (P.N. Chroston, personal communication).

b)   The Wells - Binham valley:

The valley of the tributary of the River Stiffkey which flows north-west from Binham is continued at a similar orientation north of the Stiffkey valley in the form of both a dry and a buried valley. The general line of the Stiffkey valley may also owe a debt to the fracture directions, but on a local scale this is not obvious.

c)   Weybourne:

A buried channel at Weybourne, though varying in orientation through about 10^0, is never more than 6^0 from one of the two main fracture orientations.

d)   The upper Wensum catchment:

In this area two near parallel valleys are of interest. The westernmost of these is the valley occupied by the headwaters of the River Wensum in the south and by the River Tat in the central section. These rivers flow along the same valley line but in opposing directions. Northwards from the source of the River Tat the valley continues in its dry form, though the buried channel which underlies the rest of the surface valley occurs here further to the west, but still near

parallel. The buried channel linking the line of the River Tat to that of the upper Wensum continues beneath Helhoughton Common.

The second valley line is that of the upper River Burn with a buried channel linking it with a tributary stream valley of the River Wensum.

The orientations of both valley lines vary between 130° and 140°. The dominant fracture orientation at Helhoughton is 135°.

e)   The lower Wissey catchment:

General fracture orientations of about 135° and 065° throughout the area are reflected in the lower stretch of the Wissey valley. This valley line, with a buried channel underlying much of it, extends southwards to West Toft Mere and possibly northwards as far as Barton Bendish. The northern extention is separated from the rest by the area of fen around Oxborough, across which no valley features can be traced.
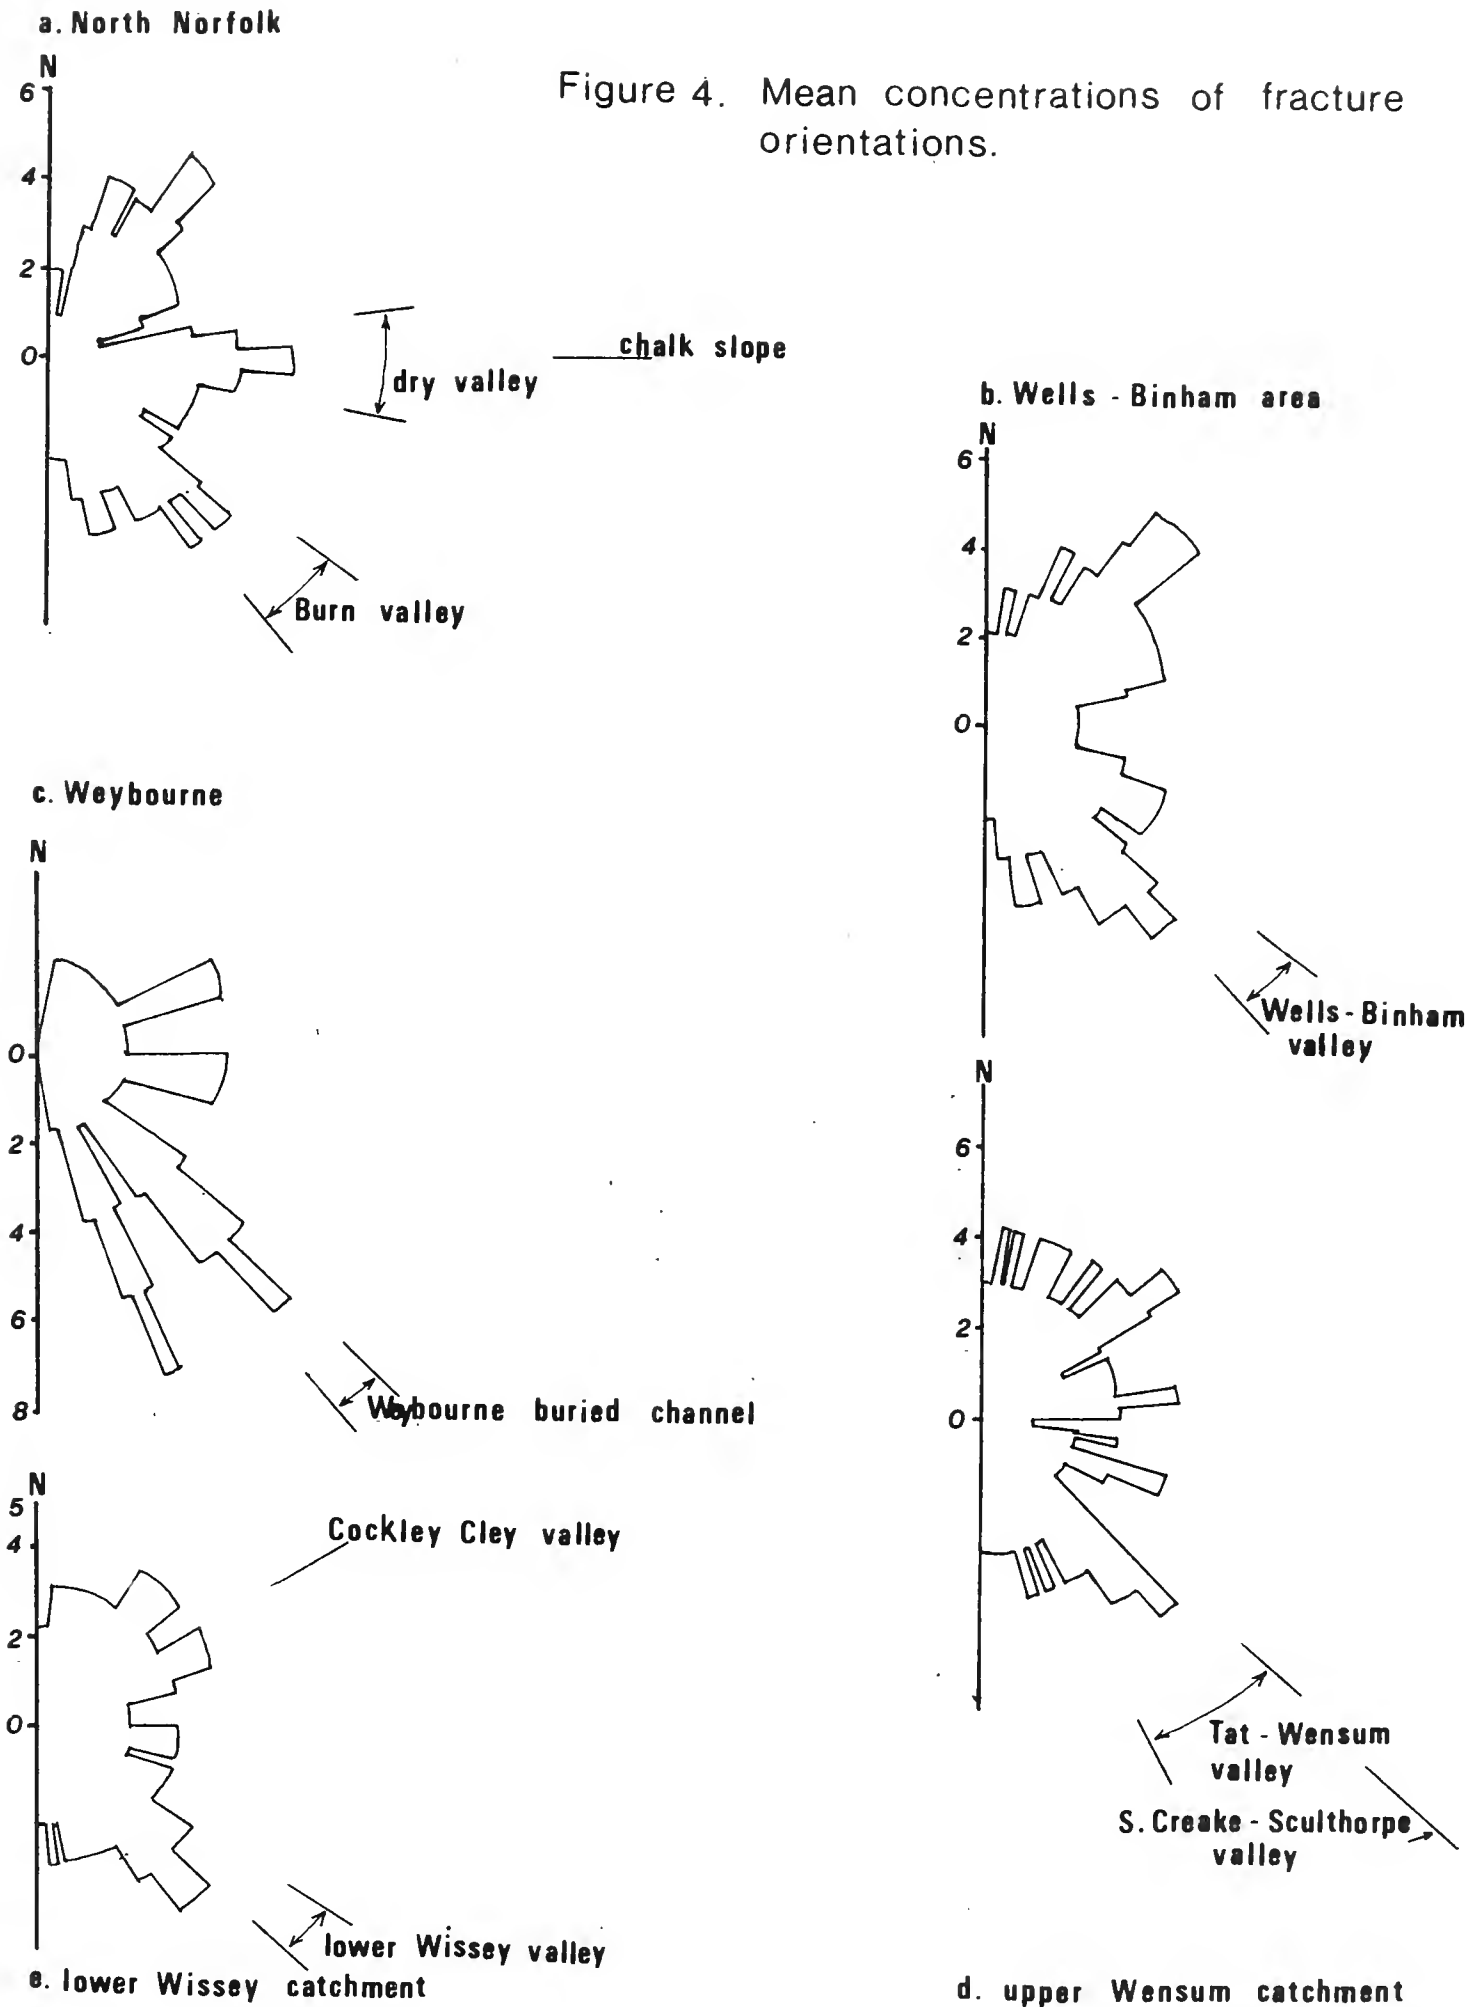

The remarkably straight valley which runs north-east through Cockley Cley is very close in orientation to the Chalk fractures at four of the exposures in the area.

A further stretch of the River Wissey follows a valley line which extends both to Tottington in the east as a tributary stream valley and to Cranwich Heath in the west as a dry valley.

DISCUSSION

The five areas taken as examples suggest a similarity in orientations between Chalk fractures and valley alignments. This is summarised in Figure 4. The rose diagrams have been constructed by taking the maximum concentration values, where dips are over 45°, at 2^O intervals of orientation on each of the stereogram plots, summing these

figures for all of the exposures within each area and then plotting

the mean values thus obtained at 2^O intervals. A single value or

range of orientations of the main valley features are also shown, thus

illustrating the close correspondence between valleys and fractures.

It is possible that the orientations of the fractures in the Chalk

have been determined by the valley alignments, as a larger scale pres-

sure release effect. Although in many cases the Chalk exposures are

within the valleys and thus cause and effect are difficult to distin-

guish, the evidence does suggest that the fracture orientation is the

controlling factor.

As has been previously mentioned, when all the Chalk exposures

throughout Norfolk are taken into account, the dominant fracture

orientations are from 050° to 060° and 130° to 140°. The valley

features in four of the five example areas considered are largely in

agreement with these orientations. Thus throughout the area there are

common fracture orientations along which in places valleys occur.

If the valleys were responsible for fracture orientations, it

could be expected that the valley-induced fracture sets would be super-

imposed upon a regional fracture set. This is not the case.

More specifically, taking the lower Wissey catchment as an

example, there are instances, such as at Stoke Ferry and South Pick-

enham, where the fracture orientations coincide not with the valley

alignments in the immediate vicinity, but at over 2 km. distance.

Were the fractures valley-induced, surely their orientations would be

expected to be those of the section of the valleys within which they

occur.

Finally, the fracture orientations at Blackdyke Farm, shown at

the extreme south-west of the lower Wissey catchment area, coincide with those of the lower Wissey valley line which is more than 11 km. away at its nearest point. The Blackdyke Farm exposure is at the very western limit of the Chalk in Norfolk, is less than 10 metres above sea level, and yet is situated at the end of a low ridge rather than within a valley. Here, at the very "feather edge" of the Chalk mass and without the influence of any valleys, the fractures are still orientated in the same directions as in the lower Wissey valley, the upper Wensum valley and at Weybourne on the north coast.

Conclusion

In Norfolk there are numerous examples of relatively straight valley features which change in "role" along their length. The unspectacular nature of the topography makes these features obscure and thus they are best identified from maps.

Taking the Tat - upper Wensum valley line as an example, it would seem that the present streams, flowing as they do in opposite directions, may be responsible for creating the present surface expression of the valley, but that the two sections of stream valley are along a common alignment must be more than coincidence. It may well be that the course of the Tat buried channel has controlled the formation of the northern part of the valley, but since this channel does not extend as far south as the section occupied by the River Wensum, it would appear that the latter part has been influenced in its alignment by the same factor as that which originally controlled the alignment of the buried channel. The measurement of Chalk fractures taken at Helhoughton suggest that this common factor is the fracturing of the Chalk.

There is no suggestion that all of the valleys of west and north Norfolk are directly influenced by the fractures in the underlying Chalk. There does seem to be a weight of evidence however that this is the case in instances cited here.

THE PLEISTOCENE SUCCESSION AT CORTON, SUFFOLK

W.K. POINTON*

Introduction

The importance of exposures in Quaternary sediments at Corton cliffs has long been established (Trimmer 1858, Gunn 1867, Blake 1890), and their regional significance is indicated by their designation as type site for the Corton Sands and Lowestoft Till (Baden-Powell and Reid-Moir 1942; Baden-Powell 1948, 1950) and the Anglian Glacial Stage (Mitchell et. al. 1973). Despite this importance, description of the sediments and stratigraphic relationships have hitherto been qualitative (Baden-Powell 1948, 1950; Blake 1890, Gunn 1867), restricted to particular stratigraphic units (Ranson 1968, West and Wilson 1968), or preliminary in approach (Banham 1971). This report gives the results of systematic study of sediments and sedimentary relationships at present exposed.

Corton is located at grid reference TM 545975, north of Lowestoft (Fig. 1a) in Suffolk. At this point the cliffs reach a height of approximately 25m O.D. Since 1969 the base of the cliff has been protected from marine erosion by a sea wall, resulting in stabilisation and colonisation by vegetation. Fresh exposures do occur, as a result of cliff failure, but this becomes progressively rarer as the basal material is not removed by coastal erosion.

Banham (1971) described a full succession of seven sedimentary units at Corton (Fig. 1b). At the time of the present study all units

were visible except the lowest, the "Cromer Forest Bed Series".

Procedure

Sedimentary structures and moist colour were studied in the field. The orientation and dip of elongate pebbles in each of the three tills were measured and the mesofabric characteristics were determined. Two dimensional preferred orientations are generalised as the resultant vector, and tested against randomness by the vector magnitude and Rayliegh significance test (Curray 1956). The orientation and dip of the "b" axis tabular pebbles in the Plateau Gravels was also measured, to determine the imbrication characteristics. These results were analysed visually.

Samples from all sedimentary units were taken back to the laboratory for further analysis. The particle size distributions were determined and the results are described in phi-units. Moment parameters were used to describe the particle size distributions of the Corton Sands and tentative comparisons made with the environmental diagnostic relationships described by Friedman (1961) and Koldijk (1968). The 4 - 16 mm sized stones from the tills were grouped according to lithologic type and the percentage frequency by weight was determined along with the percentage of calcium carbonate, in the fraction less than +3.75∅ (Dreimanis 1962). Carbonate content of the Oulton Beds was also determined.

Where possible, sample means and standard deviations have been computed and gross variability is shown by the coefficient of variation. For comparisons between the three tills the analysis of the variance is used. Unfortunately all sample populations are small and therefore the results are viewed with this inherent disadvantage in

mind.

The number of sample points studied at each site are recorded in Fig. 1b, and a summary of the results in Table 1.

Results

The Cromer Till

This deposit was the lowest unit exposed at the time of the field work. At its greatest exposure it was approximately 2.5 m thick and consisted of olive brown (2.5Y 4/4) poorly sorted, sandy till. The Cromer Till consists, on average, of 2.0% gravel, 58.2% silt and 17.2% clay (Table 1, Fig. 6), with a pronounced mode in the sand fraction.

The 4 - 16 mm size fraction consists largely of flint (61.4%) with some quartz (12.6%), hard chalk (7.2%), Jurassic and Lower Cretaceous rocks (14.1%) and metamorphic rocks (4.7%). Many of the stones such as the flint, which has a deep patina, show evidence of previous weathering. Many of the pebbles are sub-rounded. Soft chalk is absent and suggests that local chalk outcrops in central Norfolk do not contribute to the deposit. This is supported by calcium carbonate content of less than 12%.

Only one sample point for fabric analysis was studied (Fig. 2a). A resultant vector of 106° - 286° with a vector magnitude of 48% (significant at the 99% level) was determined. This direction is consistent with other results (West and Donner 1956). Folding within the till shows folds overturned predominantly towards the S.S.W. which Banham (1975) suggests indicates ice movement from the N.N.E. The fabric maximum could be a transverse peak of the type described by Banham (1966).
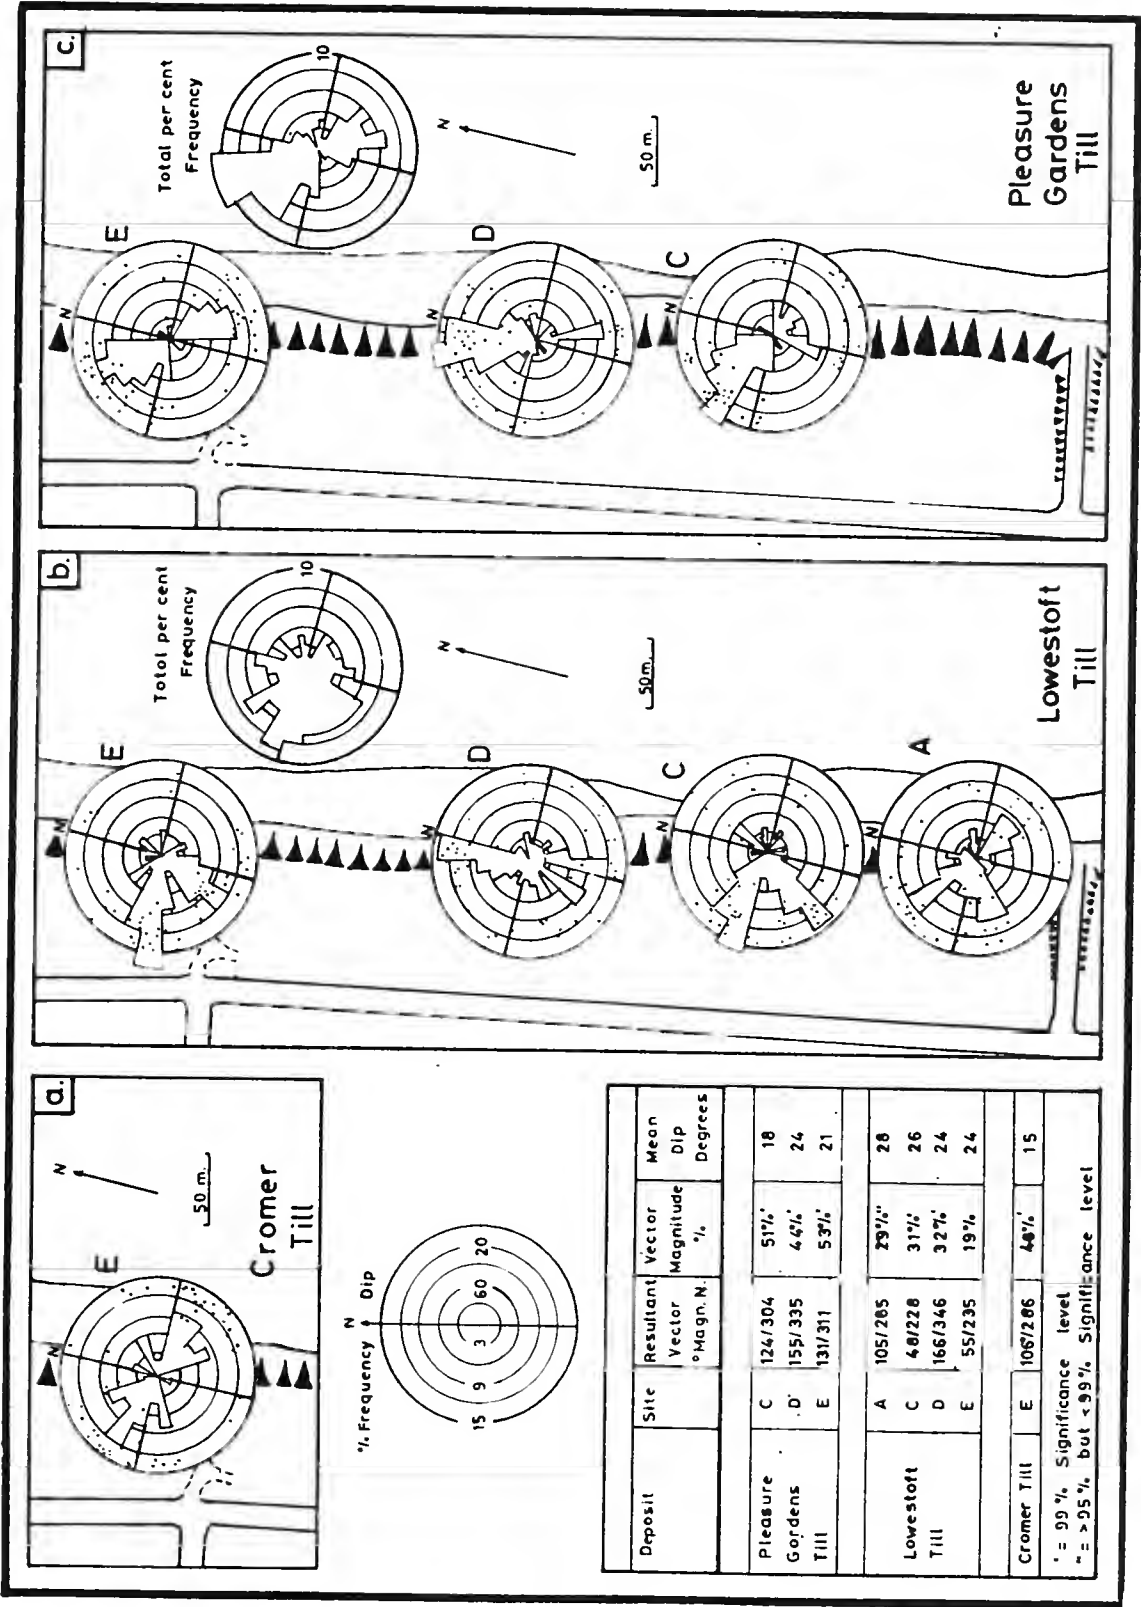

Fig. 2   Results of fabric analyses of the three tills exposed at Corton.

Key: C = Chalk, F = Flint, J.C. = Lower Cretaceous and Jurassic, I = Igneous, M = Metamorphic Q = Quartz and Quartzite

The folding indicates that the ice which deposited the till moved into the area from the N.N.E., off the North Sea. The absence of fresh chalk, and the pronounced mode in the sand fraction of the till, which indicates the closeness of the source, are further evidence of ice movement in this direction.

The Corton Sands

The Corton Sands are exposed along the entire length of the cliffs and are composed of sandy gravels, fine sands, and silts ranging in colour from light yellow (2.5Y 7/3) to orange (10YR 6/6).

The particle size distributions (Fig. 3) indicate well sorted sands and silts. Moment parameters derived for comparison with the results of Friedman (1961) and Koldijk (1968) were not conclusive but may possibly indicate deposition in a fluvial environment. In places thin laminated clays, 1-2 cm thick, were found within the silts.

The sands and silts are well bedded with some ripple bedding in the fine sands and dune bedding in the coarser sands, at the base of section E. Dips of 25° and 26° with orientations of 211° and 119° respectively indicate water flowing from an approximate north westerly direction. Silts were observed intruding into the overlying fine sands and Lowestoft Till intruded into the underlying sands (Fig. 4), these structures appear, therefore, to reflect secondary settlement, related to instability caused by inverted density gradients.

Ice wedge casts have been recorded in the Corton sands at Corton and at Burgh Castle (Ranson 1968) indicating deposition in a perma-frost environment (Pewe 1966). This is supported by the full or late glacial plant remains found in the clay lens at exposures south of Lowestoft (West and Wilson 1968).
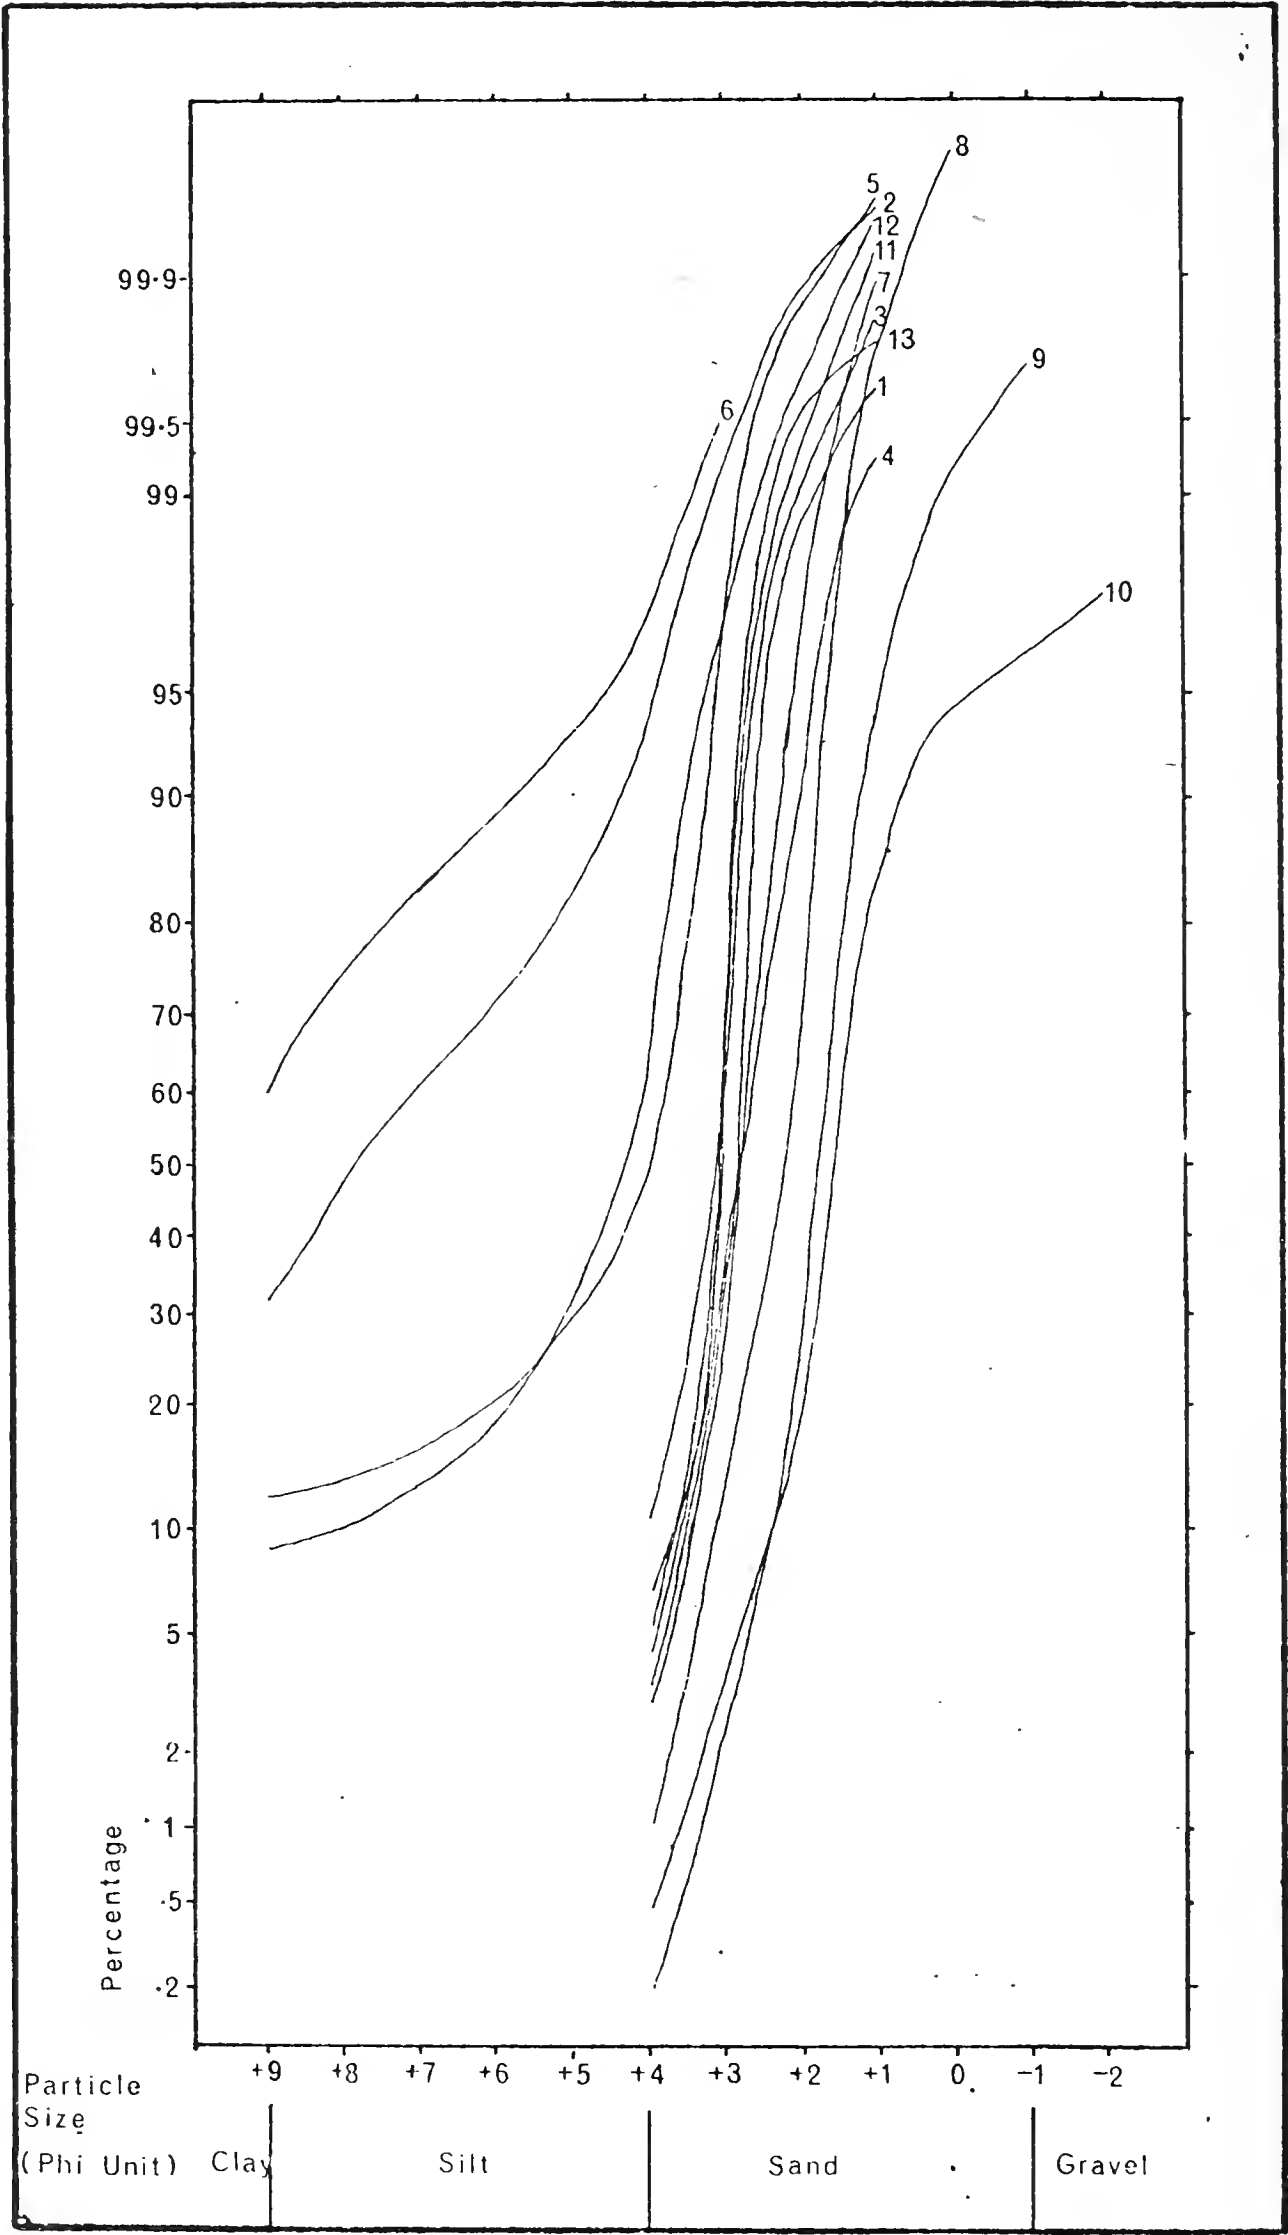

Fig. 3a

Fig. 3b

Fig. 3   Particle size distributions (a) and environment sensitive
          parameters (b) for the Corton Sands.
          F - F, - Friedman (1962). K - K, - Koldijk (1968)
          C, E & B - the sites from which samples were taken.

The occurrence of the foraminifer <u>Jadammina</u> <u>macrescens</u> and <u>Eleo-</u>
<u>charis</u> <u>parvula</u>, in the clay lens studied by West and Wilson (1968)
indicate brackish conditions. The former, found at the base of the
lens, also suggests the possibility that the lower sands are partly
marine in origin (West and Wilson 1968).

The association of the fauna, secondary structures, assemblage of
sediments and environment sensitive parameters suggest that the Corton
Sands may have been deposited in a fluvial, possibly estuarine, envir-
onment. Sedimentation occurred during a cold period after wastage of
the Cromer Till ice but prior to transgression by Lowestoft Till ice.
The Lowestoft Till

The Lowestoft Till comprises a poorly sorted, stiff, dark grey
(N3) clay. At all sites its thickness was greater than 2 m, but it
was difficult to obtain more accurate measurements because of slumping
which also limited the choice of sample sites to the top 2 m of the
deposit.

The deposit contains on average 4.9% gravel (Vc = 37%), 11.2%
sand (Vc = 9%), 41.2% silt (Vc = 8%) and 42.7% clay (Vc = 9%), (Table
1, Fig. 6).

The 4 - 16 mm size fraction is variable and consists of chalk
69.2% (Vc = 8.0%), flint 11.3% (Vc = 45.0%), Lower Cretaceous and Jur-
assic 17.8% (Vc = 35.0%) and quartz 1% (Vc = 80%). A carbonate con-
tent of 40% suggests that much of the finer fraction is composed of
comminuted chalk of which the most likely source is central and west
Norfolk.

The till fabric results for all samples show orientations which
differ from random at a level greater than 95% (Fig. 2b). The mean

Fig. 4   Load deformation structures in the Corton Sands.

strength of the resultant vectors is 27.8% (Vc = 21%) and the mean dip
26.5^o (Vc = 7%).   Individual vector strengths are distributed system-
atically from the bottom to the top of the section, with stronger val-
ues at the base.   Orientation trends range from 48°/228° to 166°/346°
and along with mean dip values are apparently randomly distributed.
This reflects the absence of a regional energy source (Rose 1974) and
may suggest that depositional characteristics were influenced by local
conditions.

Results obtained for the Lowestoft Till at Corton show similarit-
ies to those recorded by Perrin, Davis and Fysh (1973), for the Lowes-
toft till in Suffolk, particularly with respect to the high clay and
calcium carbonate contents (49.8% and 43% respectively in Perrin et.
al. 1973).

The stone content and calcium carbonate content suggest that the
material, of which the Lowestoft till is composed, was derived from a
westerly direction.   The mesofabric properties suggest that deposition
was influenced by local factors, such as those associated with melt-
out processes associated with the later stages of glacial decay.

The Oulton Beds

These lie immediately above the Lowestoft Till and consist of
grey (N/4) to greyish yellow (2.5 YR 4/3), clayey silts, overlain by
sandy silts and fine sands.   They indicate relatively still water dep-
osition with occasional current flow.

Mean calcium carbonate content of 32% suggests deposition from a
source rich in calcium carbonate such as the Lowestoft Till.   Altern-
atively this could be due to a high faunal activity but there is no
evidence to support this (Banham 1971).

The particle size properties, colour, calcium carbonate content and stratigraphic relationship to the Lowestoft Till suggest that the Oulton Beds consist of slow flowing or still water sediments derived from the Lowestoft Till. The gradual change from clay to silt and fine sand suggest a shallowing sequence, probably associated with a proglacial lake such as are found at the present day in Spitzbergen (Boulton 1968).

The Pleasure Gardens Till

The till is of variable thickness (observed range .9 m to 2.5 m) with definite chalky banding displayed at all sites. Colours ranges from greyish white (N/7-N/8) within the chalky bands, to dark grey (N/31N/4).

The Pleasure Gardens Till is poorly sorted (Table 1 Fig. 5), with an average of 1.7% gravel (Vc = 65%), 19.2% sand (Vc = 35%), 52.1% silt (Vc = 22%) and clay 27% (Vc = 57%). The high silt and clay content again suggest that Mesozoic clays form the predominant source material.

The lithology of the 4 - 16 mm size fraction is characteristically variable and composed largely of chalk 63.2% (Vc = 38.0%), and flint 26% (Vc = 89.0%), with the remainder made up of Cretaceous and Jurassic rocks.

All samples are rich in calcium carbonate (mean 69%) but there is considerable variation (Vc = 28.0%) between samples. Examination of the carbonate content and chalk percentage of the gravel fraction indicates a tentative relationship between the two. The sample with the highest percentage of chalk (84%) had the lowest carbonate content (47%) in the matrix. Similarly, with the other samples, as the chalk

gravel decreased the carbonate content of the matrix increased, sug-
gesting the possibility of some comminution of the chalk during sub-
sequent reworking of the deposit.

The strong mesofabric properties and evidence of comminution of
the chalk gravel, indicate deposition by dynamic processes. The mech-
anical composition suggests a glacial origin for the sediments. These
properties, plus observed chalky banding in the Pleasure Gardens Till,
have been associated with the development of flow tills in Spitzbergen
(Boulton 1968).

The very high local rock content is consistent with what might
be expected if the material is brought to the surface of the glacier
by englacial shearing at the snout (Boulton 1968). Subsequent melt-
ing, would generate high pore water pressures causing instability
(Boulton 1968) resulting in flow.

The Plateau Gravels

Immediately above the Pleasure Gardens Till are the Plateau
Gravels which consist largely of medium gravels, with fine to medium
sands. The modes in the gravels occur in the 8 mm to 16 mm range and
the 0.5 mm to 1 mm range indicating possible bedload and saltation
components in a fluvial system, or transitional, lag deposits, bet-
ween the surf and swash zones on a beach (Visher 1969).

The deposit is strongly imbricated (Fig. 4) but with a variety
of modal directions. Such properties might suggest either a braided
or meandering channel.

The Plateau Gravels appear to have been formed by a shifting
and variable fluvial process, such as that associated with a high,
but fluctuating, discharge and a plentiful sediment supply. Such

Fig. 5   Fabric analysis results for the Plateau Gravels.

(Key as in Fig. 2).

conditions are typical of a braided rather than a meandering fluvial

system (Allen 1970, Leopold and Wolman 1957). The stratigraphic rel-

ationship to the lower deposits suggest that they were formed by

meltwater streams, highly charged with glacially derived sediments,

in front of a melting glacier margin.

Discussion

a)   Comparisons of the three tills

The three till units differ with respect to calcium carbonate

contents. The Cromer till is deficient in $CaCO_3$, whilst the content

of the Lowestoft and Pleasure Gardens Till is high to very high.

The particle size distributions (Fig. 6) show that the Lowestoft

and Pleasure Gardens Tills are similar in most respects, except that

the latter is more variable. Possible differences in the gravel

fractions, and $CaCO_3$ content, of the two tills, are most probably ac-

counted for by comminution of the chalk gravel during the prevailing

depositional conditions of the Pleasure Gardens Till. Both tills are

different from the Cromer Till, particularly with respect to sand silt

and clay fractions.

The lithological compositions of the gravel fraction of the three

tills shows large differences in the chalk, flint and quartz contents,

between the Cromer and the other two tills. In contrast differences

between the Lowestoft and Pleasure Garden Tills are small. This sug-

gests a similar provenance for the Lowestoft and Pleasure Gardens Till

but a distinct difference in provenance between these and the Cromer

Till.

The evidence suggests that the Lowestoft and Pleasure Gardens

Tills are probably related to the same glacier, derived from the west,
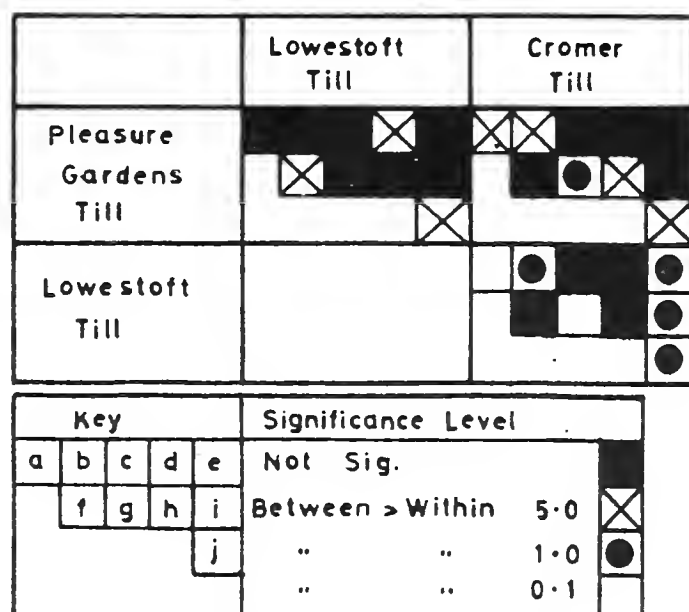

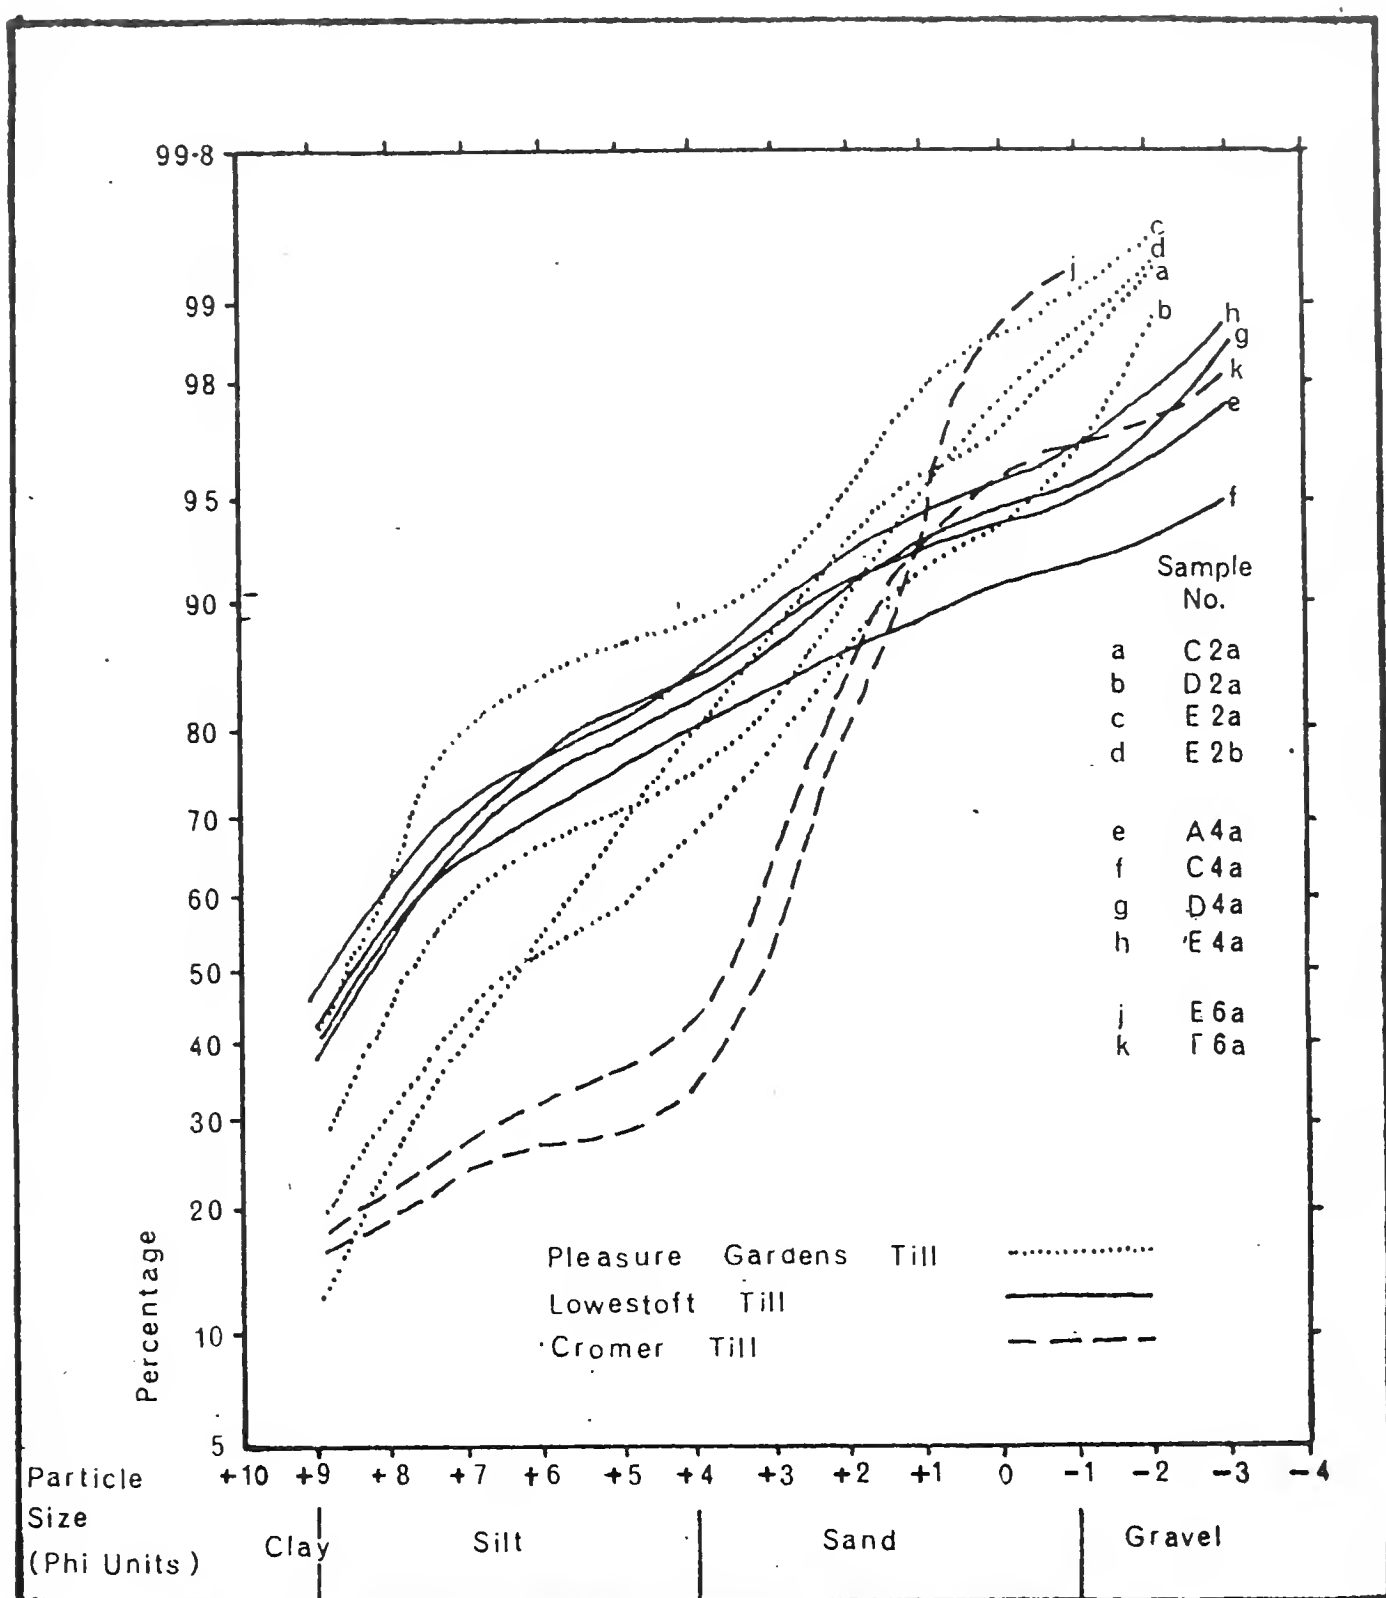

Fig. 6   Particle size distributions of the three tills at Corton
          and the results of an analysis of the variance test.
          a - chalk, b - flint, c - Cretaceous, d - Jurassic,
          e - quartz, f - gravel, g - sand, h - silt, i - clay,
          j - CaCO$_3$.

and the differences that do occur are related to the mode of deposition (Banham 1971). The Cromer Till, however, is different from both the Lowestoft and Pleasure Gardens Tills with respect to $CaCO_3$ content, sand, silt, and clay contents and the major lithological groups, suggesting deposition from a source unrelated to the other two tills.

b)   The age of the deposits

The Lowestoft Till, Oulton Beds, Pleasure Gardens Till and Plateau Gravels represent a possible sequence of glacial, pro-glacial, flow-till and outwash deposition without any evidence of a significant hiatus. As the Lowestoft till can be dated as Anglian by relation to biostratigraphic interglacial deposits elsewhere in East Anglia, this age is applied to the whole of the depositional sequence. Since the Cromer Till was deposited before the Lowestoft till sequence and can be seen at Corton to lie above deposits of Cromerian Age, it must therefore also be ascribed to the Anglian. It would appear therefore that there is evidence of the two separate glacial episodes both of which occurred during the Anglian Stage of the Middle Pleistocene.

Conclusion

The evidence from Corton suggests therefore that the Cromer Till was deposited by ice which moved into the area from the E.N.E. The development of the Corton Sands indicate that the glacier retreated and was replaced by a fluvial possibly estuarine environment in which sands, silts, and clays were deposited. Ice-wedge casts (Ranson 1968) and cold environment flora and fauna (West and Wilson 1968) indicate that a periglacial climate persisted throughout their deposition.

In turn the area was then overrun by the glacier that deposited the Lowestoft Till. This glacier moved across the area from a west-

Table II   The Corton Stratigraphy presently exposed and the suggested

division into sub-stages (After Mitchel et al 1973)

	Deposit	Sub-stage	Stage
6.	Plateau Gravels		
5.	Pleasure Gardens Till	Lowestoft	
4.	Oulton Beds		
3.	Lowestoft Till		Anglian
2.	Corton Beds	Corton	
1.	Cromer Till	Gunton	

erly direction having passed over and entrained the Jurassic and
Cretaceous sediments to the west. The upper part of the till unit
analysed at Corton appears to have been deposited during the later
stages of this episode, when melting was the predominant process.
Retreat of the ice margin appears to have been followed by proglacial
lake development and sedimentation in which the Oulton Beds accumul-
ated. These lake sediments were in turn buried beneath flow till
units derived from the same ice sheet until mud flow deposition was
replaced by outwash sedimentation and the Plateau gravels were aggrad-
ed.

The sequence currently exposed at Corton can be grouped into
three sub stages for which the following names (Table II) Lowestoft,
Corton, and Gunton, have been suggested (Mitchell et. al. 1973).

Acknowledgements

The author thanks his wife, Susan, for her considerable help with
field work. Acknowledgements are also due to Dr. P. Banham for the
opportunity to discuss the results. Finally, he would like to thank
J. Rose, for his advice and supervision throughout the project.

REPORT ON A FIELD MEETING AT DOBB'S PLANTATION, WROXHAM (TG 273158),
SEPTEMBER 1977

P.G. CAMBRIDGE*

The decision to attempt a dig in this area was taken because of
the special interest of the Icenian Beds in the Bure Valley. At one
time there were a number of pits near Belaugh, Wroxham, Coltishall and
as far up the valley as Aylsham. Many of these pits were originally
worked for chalk and the overlying beds, mainly pebbly sands, were
dumped back into the pit. The pebbly sands were shelly in parts and it
was noted that the bivalve, Macoma balthica was present in the upper
beds only. For this reason early writers suggested that there was an
overlap of the Norwich and Weybourne Crags in this area.

The area chosen was a small tributary valley of the Bure, Dobb's
Beck, with a line of several pits, now overgrown, marking the outcrop
of the Chalk. The most southerly of these, Limekiln Hole, alongside
Dobb's Lane, was recorded by Woodward (1881) who noted casts of shells
in ironstone. He noted that the next pit, "three furlongs to the north"
showed shells in abundance and gave the following section:

			Feet
	3.	Pebbly gravel with shells up to the	
		surface	6
Upper Crag	2.	Laminated clay	1/2
	1.	Shell bed, sand and gravel	2

Chalk with flints.

It was planned to excavate a section in this pit but difficulty

* 258 Bluebell Road, Norwich NR4 7LW

was experienced in deciding the exact site. A large pit was located in the area marked on the map as Dobb's Plantation. The pit is largely backfilled and has mature trees growing in it but traces of shells were found near the eastern face and work started at this point. Digging was in a series of steps starting from the base of the pit. By midday the surface of the chalk was exposed about halfway up the slope and the lower part of the digging was then abandoned. With the aid of fresh reinforcements from the Ipswich Group the upper part of the section was cleaned and widened, offering a good working section in shelly Crag. After this was measured and recorded, members collected specimens and samples, a series of which is now in the museums at Ipswich and Norwich and in the author's collection. Details of the section are given elsewhere in this Bulletin.

Our thanks go to Mr. Trafford, of Trafford Estate for kind permission to examine the site, which it should be noted is on private land and needs permission to visit.

A SECTION IN THE "BURE VALLEY BEDS" NEAR WROXHAM.   (TG 273158)

P.G. CAMBRIDGE*

The section was excavated in September 1977, a description of which has
already been given (Cambridge, 1978), and is illustrated in Fig. 1.

The History of Research on the Bure Valley Beds

The fossiliferous, pebbly sands and gravels of the Bure Valley
were separated from the Norwich Crag by S.V. Wood and F.W. Harmer
because of the occurrence of <u>Macoma balthica</u>. They regarded them as
lower glacial and in 1866 gave the name Bure Valley Beds. Harmer (1894)
wrote: "The late Mr S.V. Wood and I have classed the Bure Valley Gravels
as the lowest horizon of the Glacial Series. H.B. Woodward of the
Geological Survey regards them as belonging to the Crag period." They
were recognised as marine, "the pebbles water-worn and rounded .... of
a dark red colour."

On the other hand Prestwich (1871) divided the Icenian into Norwich
Crag, Chillesford Clay and Westleton Shingle. He regarded most of the
fossiliferous beds, with or without <u>Macoma balthica</u> as Norwich Crag.
His Chillesford Clay, which Harmer also considered represented a well
marked horizon, is not now recognised outside the type area near Chil-
lesford and Aldeburgh in Suffolk. Reid (1890) commented "such laminated
clays are characteristic of the Pliocene (sic) beds of Norfolk, they
are not confined to one horizon, they were not all deposited at one
particular time and their absence is not necessarily the result of de-
nudation". Much of Prestwich's Westleton Shingle in the area would be
classed with the Bure Valley Beds.

* 258 Bluebell Road, Norwich.

Similar deposits with M. balthica on the coast were called the Weybourne Crag and in the early days their relationship was in dispute. Thus Prestwich correlated the Weybourne Crag with the Norwich Crag while S.V. Wood jr. considered it should alternate with the glacial deposits. Harmer in dividing up his Icenian period placed the Weybourne Crag at the top of the series as the youngest division of the Crag characterised by the first appearance of M. balthica which he designated as the zone fossil. This fitted in with his assumption that the Crags were deposited in a series which were geographically progressing to the North. Since the Bure Valley Beds also contained M. balthica they were considered the inland equivalent of the Weybourne Crag.

In the Lexique Stratigraphique the Bure Valley Beds are considered as "The inland equivalent of the Weybourne Crag which occurs on the coast, having the same fauna". (Baden-Powell 1963).

It was noted quite early (Woodward 1881) that M. balthica occurred only in the upper beds of the Bure Valley Beds leading to the suggestion that at this point the Weybourne Crag overlapped the Norwich Crag. This strengthened Harmer's interpretation of the Crag sequence with Red Crag seen resting on Coralline at Ramsholt Cliff, Icenian on Butleyan Red Crag at Chillesford and Weybourne Crag on Norwich Crag in the Bure Valley.

Until comparatively recently no further work has been done on the Bure Valley Beds, because of the overgrown condition of the exposures. Harmer (1920) wrote "Unfortunately none of these sections is now accessible". No new sections have been reported since then. However, West (1968) published a table of Lower Pleistocene stages based on pollen spectra in which essentially the Weybourne Crag was shown as the same

age as the Norwich Crag. The main difficulty to acceptance of this view
is the complete absence of M. balthica in the rest of the Icenian with
no apparent physical barriers to its spread. Accepting that the pollen
flora is the same there is still no reason why the marine beds with M.
balthica should not be younger than those without and the succession in
the Bure Valley would seem to bear this out. In this view the Weybourn-
ian marine stage could be described as late Pastonian in terms of ter-
restrial pollen stages, a compromise dictated by the fact that bio-
stratigraphical units tend to differ when a different Phyllum is used.

In 1977 P.E.P. Norton investigated the mollusca of another pit
near Wroxham (personal communication) but the results have not yet been
published. It is clear that this is an important area in determining
the Icenian stratigraphy and further work is justified.

Description of the section

The surface of the Chalk showed no unusual features. The marine
Crag consists of 1.35 metres of sandy gravels with several distinctive
shelly beds. There were no sharp divisions between the various gravels.
The lowest bed consisted of light coloured very sandy gravel with num-
erous well preserved shells, especially Macoma. This is followed by
half a metre of badly sorted gravel, including ovoid, well rounded
flints with chatter marks; angular flaked flints and detached flakes,
some very fresh looking; eroded flints possibly from a land surface;
chalk fragments. In the smaller pebble fractions quartz/quartzite peb-
bles are not uncommon. Small pebbles were very abundant in this layer
but very large, unworn flints up to 30 cm across, also occur.

At 50 to 60 cms above the Chalk is an intermittent ferruginous
layer of flattened concretions. Similar concretions are also scattered
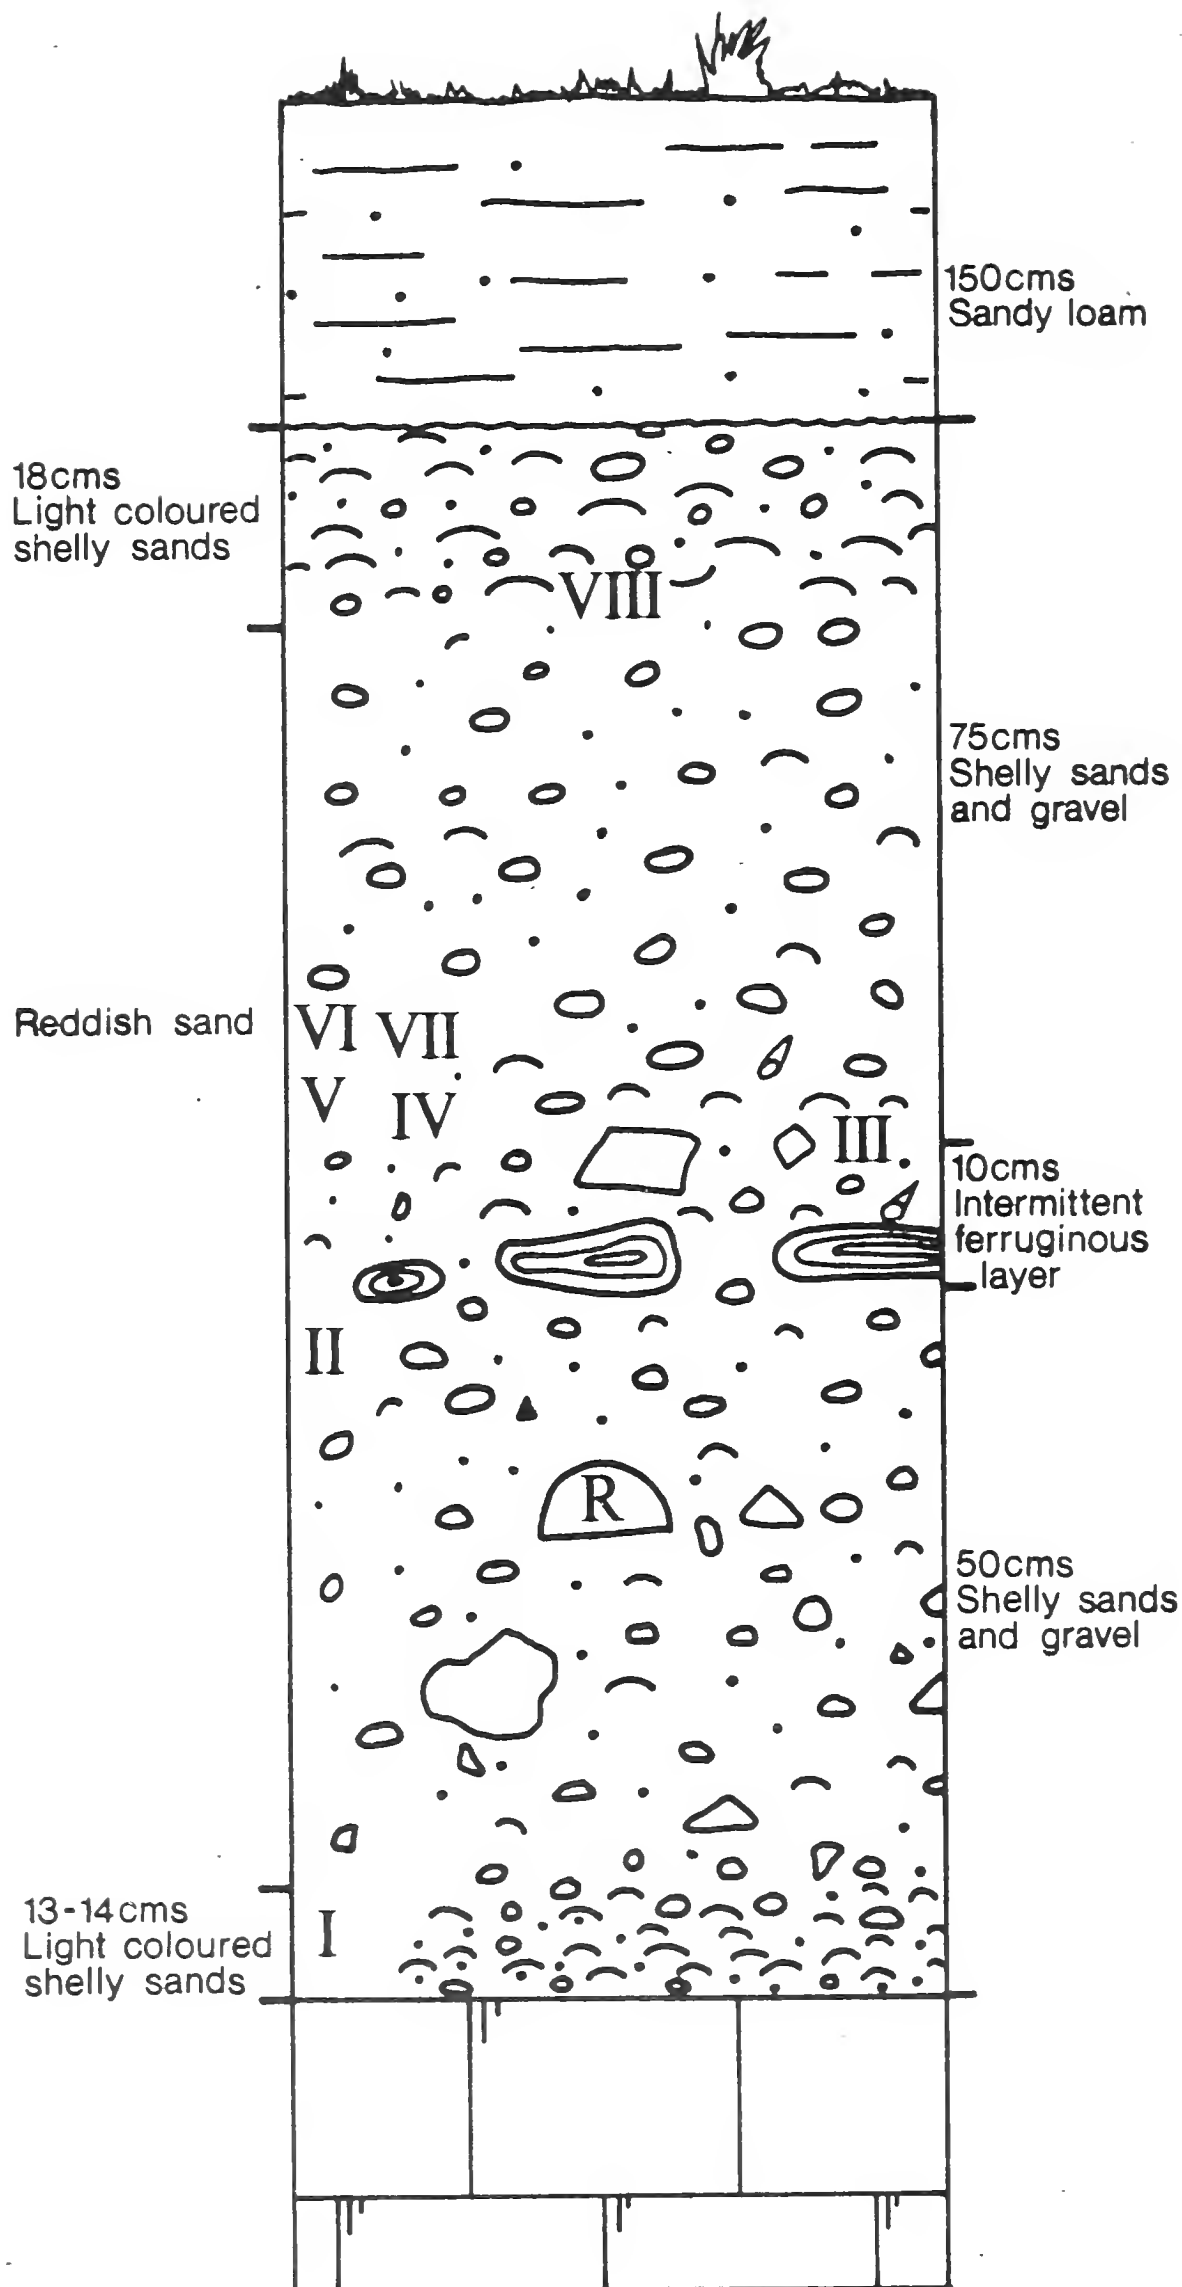

Fig. 1   BURE VALLEY BEDS

DOBB'S PLANTATION, NR WROXHAM HALL

Roman numerals indicate positions where samples
were taken. R = "rostrocarinate" flint.

throughout the section. The sand and gravel at this horizon is distinctly red in colour. Finally some 75 cms of shelly sands and gravel follow with a distinct bed of light coloured worn shells at the top.

Over the Crag is a thick layer of sandy loam, probably hillwash and soil from the ploughed field above. A scatter of pebbles on the field included many flints, as well as quartz/quartzites and pieces of very fossiliferous crinoidal chert.

The lower part of the gravels is decidedly more angular than the upper and large flints persist to about 70 cms above the Chalk. There is no 'Stone Bed' on the Chalk as is frequently the case at the base of the Crag.

Palaeontology

Samples averaging about 4 kgs each were taken, especially from the more shelly portions of the gravels.

Sample numbers are shown in Roman numerals in Fig. 1. Samples III and V were ironstones; the faunas from the other samples are listed in Table I. Considering the small size of the samples the fauna is a large one. Samples VI and VII can be considered to come from one bed. Where less than five specimens were found the actual number is shown in the table. The fauna throughout is dominated by the bivalve Macoma. Sample I.

The basal bed is especially rich in vertebrate remains. Apart from fragmentary mammalian remains the fish fauna is much larger than is usual in the Icenian. The shark Hexanchus is recorded from the Red Crag but apparently not from the Icenian and there are several other fish teeth not in the table as they are not yet fully identified. It is possible that some of the teeth are derived. In fact the two very

small fragments of <u>Turritella</u> <u>incrassata</u> are probably also derivative.

Sample II.

The shells are very fragmentary and worn.

Sample IV.

A large, well-preserved fauna. One example of <u>Macoma</u> with paired

valves.

Sample VI and VII.

The gastropods seem well-preserved and include <u>Beringius</u> <u>turtoni</u>

which is not recorded from the Icenian although found in the Red Crag

and also as a recent species. Many of the larger bivalves are very

worn and rounded but some quite fresh juveniles occur.

Sample VIII.

Many well-preserved shells.

Conclusions

The fauna as a whole is similar to that of many other Icenian

sections, and would certainly be larger if further samples were examined.

Woodward's early list of 1881 included only 15 species. The section is

not so easy to interpret as that given by Woodward because the thin

seam of laminated clay which divided his Bed 3 from Bed 1 was not pres-

ent. However this may have been merely a local phenomenon and the clay

might be present elsewhere in Dobb's Plantation pit.

The presence of <u>Macoma</u> <u>balthica</u> in the top of the section suggests

correlation with the Weybourne Crag while the lower section bears some

resemblance to the section in Norwich Crag at Blake's pit (see Bulletin

No 27). In both the lower beds contain material which is suspected of

being derived from earlier Crag beds. Both <u>Nucella</u> and <u>Littorina</u> are

uncommon while <u>Chlamys</u> <u>opercularis</u> and <u>Venus</u> <u>fasciata</u> are common as at

Bramerton and Whitlingham. Rostrocarinate flints occur at both sites.

Sample 4 resembles the fauna of the Upper Shell Bed at Bramerton in some respects, such as a larger number of Littorina and Nucella and the appearance of Macoma calcarea which may indicate some cooling. The absence of some Bramerton species may result from a difference in facies. In the Yare Valley at Postwick Village, Bramerton and Whitlingham, the shelly Crag is followed by ferruginous beds without fossils and it is just possible that these compare with the ferruginous layer and red gravels in the middle of the section at Dobb's Plantation.

Rostro-carinate flints

Like most Crag deposits the pebbles consist almost wholly of flint, although there is a small proportion of chalk pebbles especially in the lower part of the gravels. The pebbles of the lower gravel are also considerably more angular than the upper and include a number of 'flakes' and 'cores'. These terms are more generally applied to artifacts and are used here for want of better names, but without implying any kind of artificial origin. Pebble size varies considerably and some very large flints occur. Some of these are unworn Chalk flints with cortex still present, other were cores with many flakes removed, patinated and ironstained. One of these, marked (R) in Fig. 1., approaches the form described as 'rostrocarinates'.

At the beginning of the century many prehistorians were preoccupied with finding evidence of man's presence in the Crags. J.R. Moir carried out a series of special excavations in the Red and Coralline Crags, and figured a number of crudely flaked flints which were claimed to be of human origin. Other evidence ranged from the ridiculous (the shell portrait from Walton-on-the-Naze) to the disputed (shark teeth perfora-

ted at the point of balance. Most of the supposed evidence for the presence of man in the Crags is discussed by Sainty (1929). To date the only known human remains is a jawbone from the Red Crag at Foxhall, near Ipswich. It cannot be proved whether this was actually a true Red Crag fossil as its present whereabouts is unknown.

Lankester (1915) selected from Moir's collection a number of beak shaped flints, and one of these from the Norwich Crag at Whitlingham was selected as a test specimen. The main features of this 'implement' type were a flat lower surface, supposedly produced by one cleavage blow, with the two sides trimmed to form a keel or carina, a wide solid butt and a beaklike point at the other end. Ideally the projected form was symmetrical, although it was admitted this was not always achieved.

In the following decades man's presence in the Crag was discounted on the grounds that the deposits were too old, or that the climate at the time was too cold. Since then artifact-producing primates have been discovered in Africa in coeval deposits. The presence in the Crag of land and freshwater shells now found in North Africa and around the Mediterranean, suggests that the land climate was by no means unfavourable. If slow-moving mammals like the hippopotamus could reach the area during the Eemian Interglacial why should more mobile primates not do so? With this in mind the author collected flaked flints from the base of the Norwich Crag in the area around Whitlingham and Bramerton. Examples showing the general features of a rostrocarinate were not uncommon but none was as perfect as the type specimen. Indeed every gradation occurred between implement-like forms and rough flints. All had one feature in common; they were formed from large, rounded and worn flints, broken to give a plano-convex shape. The flat ventral

surface was generally the most heavily patinated and there were often a number of short, parallel scratches on it. Lankester (1915) noted these scratches and suggested they might have been caused by use or by ice action.

One thing was apparent. The rostrocarinates could not have been purposefully formed in the way that was suggested. There is a difference in the patination of the flake scars which shows that they were not all made at the same time. The flat ventral surface was always more heavily patinated but there are also differences between the scars on the sides and dorsal surface. If the specimens are not artifacts then how were they formed?

The specimen (R) at Dobb's Plantation was found in situ with the plane face downward and is so battered that most of the original cortex is removed. Small scratches are present on the ventral surface, 15 to 20 mm long, in two series at an angle of about 30° to each other. Occurring as it does in a sandy gravel, the ventral face would have rested on points of underlying flint pebbles and any movement with pressure from above could cause the scratches observed. Pressure against underlying flint pebbles near the edges would cause flakes to be detached at a high angle to the ventral surface and so form the carina. Such movements might have been caused by wave pressure during deposition, or by subsequent movements in the deposit caused by glacial loading, solution of carbonates or other causes. Cases of natural flaking of flints in subsoil are discussed at length by Warren (1923). Several very fresh looking flakes were found in the lower gravel at Dobb's Plantation suggesting that some flaking subsequent to deposition has occurred.

Whether the 'rostrocarinates' were formed entirely in situ in the base of the Crag cannot be proved. The battering of some examples suggests a varied history. A very considerable time elapsed between the emergence of the Chalk surface and the deposition of the early Pleistocene Crag. The large number of a similar shape in the Stone Bed or near the base of the Norwich Crag suggests a common origin. It can be concluded that human agency in making the Norwich Crag rostrocarinates is disproved by the differences, in the same specimen, of patination of flake scars.

DEPOSITS MARGINAL TO THE RED CRAG BASIN

R.G. Dixon*

Introduction

Several deposits, such as the Creeting Beds, lying to the west of the main Red Crag basin have been assigned a Red Crag age and a marine origin by many workers. A recent examination of these deposits has shown that some previous assumptions may be unfounded, and that the age and origin of some beds is doubtful. This brief contribution is in part a review of previous major work on these deposits. It also serves to introduce some quantitative results, which were all too lacking in the earlier literature. It will become apparent, moreover, that a great deal of work still needs to be carried out before firm conclusions can be reached or should be accepted.

The Creeting Beds

The age and origin of deposits to the west of the main shelly Red Crag mass are somewhat enigmatic. The best known sections are those at Creeting and Bramford, but the deposits can be traced from Stowmarket and Wickham Market to the Grundisburgh district. For the most part the sediments are clean, white, unfossiliferous sands with a basal pebble bed, and overlie Reading Beds, Thanet Sands and, further to the west, Chalk. The sands are overlain unconformably by quartzose gravels (White Ballast) and silts, which have been dated as Beestonian (M. Pleistocene) by Turner (in Mitchell et al 1973).

The basal pebble bed commonly 0.3m thick, consists of flint pebbles in a brown, muddy fine sand matrix. Phosphatic nodules, shark's teeth,

Figure 1. Particle size distribution curves of Battisford, Creeting and Sudbury Pebble Beds.

OMMISSION

This diagram should be included with the paper
by R.G. Dixon "Deposits marginal to the Red Crag
Basin" as published in Bulletin No. 30 (1978).

The editor apologises to the author for the
ommission.

fragments of ray palate and bone also occur, having been derived from the underlying Tertiary deposits.

The pebble bed is generally similar to that at Battisford, but differs, however in containing no shell debris or even casts or moulds, such as are common at Battisford and in basal deposits of the Lower Red Crag. The Creeting pebble bed also contains a much higher mud content than its supposed equivalents at Battisford or in the Lower Red Crag, which contain no mud.

The overlying Creeting Sands are well sorted fine or medium sands, sometimes with small or medium scale false bedding, and are typically 3m thick. The sands are very similar in lithology and structure to fluvui-glacial deposits at Haugh Lane, Woodbridge, which differ, however, in containing a comminuted, abraded and strongly etched, derived Red Crag fauna. The Creeting Sands do contain foraminifers in a similar state of preservation, but less commonly, and no mollusc debris.

Whitaker (1874), Reid (1890), Boswell (1928) and others suggest a Red Crag age for the deposits, based largely on the similarity to the Red Crag, and dissimilarity to the drift deposits, and the occurrence of phosphatic nodules at the base. However, the Creeting Beds are neither red, nor crag (i.e. shelly sand), the state of the foraminifers suggests almost certain derivation (and only indicate a maximum age for the deposit), and phosphatic nodule beds can occur in any deposit resting on the London Tertiary series. The pebbles are of local origin, and thus indicate a pre-Baventian age, for it is not until the Baventian that exotic pebbles became common in the East Anglian Pleistocene (Hey 1976).

Spencer (1967) suggests that the sands are of Red Crag age, since

they contain a supposedly Villafrancian deer fauna, including Cervus
falconeri, C. tetraceros with Ursus ?arvenensis and Castor ?veterior.
This fauna possibly indicates merely a Lower Pleistocene age (not just
Red Crag), but could equally well be derived, and correlation cannot be
certain.

More reliable evidence of a marine origin is recorded by Markham
(1971; pers. comm.) who notes the rare occurrence of articulated Mytilus
edulis, barnacle fragments, a questionable Neptunea contraria and casts
and moulds of other molluscs from the pebble bed at Bramford. If the
Mytilus are articulated, as Markham suggests, they are unlikely to be
derived, and tend to suggest a littoral origin for the pebble bed. But
this evidence is still not conclusive of a Red Crag age. Spencer (1967)
records the rare casts of Turritella. Also, trace fossils, comparable
but not identical to those found in the Red Crag (S.S.), have recently
been found at Bramford. This evidence would tend to confirm a marine
origin for these deposits.

The Battisford Beds

The Creeting Beds do provide a link between the Red Crag and a
fossiliferous pebble deposit at Battisford, which rests unconformably
on Chalk. Some 3.5m of pebbles are overlain by 1.8m of pale grey/yellow
sands, which are overlain by glacial quartz sand and gravel, and by
till. The pebbles are predominantly of flint, but phosphatic nodules
occur and there is much derived Upper Cretaceous material - belemnites,
crinoid ossicles. Cidarid spines and Inoceramus fragments, though Chalk
pebbles are uncommon. Indigenous and derived vertebrate remains are
also common.

The mollusc assemblages are not comparable with assemblages later

than Thurnian (i.e. early Norwich Series), but indicate an age younger

than Gedgravian. All the molluscs recorded from the pebble bed are to

be found in the Red Crag, and a Red Crag age is assumed for them.

Table ·1 shows the percentage frequencies of molluscs obtained in a

sample from the Battisford Pebble Bed (method after Norton, 1964). It

can be seen that nearly 20% of the shells were too worn to be identified

to specific level; this indicates a high degree of transport, and there

is little doubt that much of the assemblage is allochthonous. The

assemblage compares most favourably with certain assemblages from Lower

Red Crag in the Waldringfield/Newbourn district, where a Venerupis-rich

sublittoral shell gravel association occurs. However, Mytilus edulis

occurs in high frequencies, and many Mytilus valves are articulated.

This suggests that many of the sublittoral shells have been transported

to a shallow water or littoral environment. The high frequencies of

large, easily rolled gastropods, e.g. Neptunea and Turritella can also

be accounted for by preferential transport and their hydrodynamic

behaviour. The presence of ?Arenicola tubes is supporting evidence of

shore-line conditions. The presence of articulated shells, e.g. Macoma

obliqua and Mytilus edulis, indicates that derivation from a Red Crag

source is extremely unlikely. The sands, on the other hand, contain no

shell debris, and the finely preserved sedimentary structures suggest

that no decalcification took place. In other words, no shell debris was

available for deposition. However, small trace fossils identical to a

type found in the Red Crag are abundant at certain horizons, invalida-

ting any suggestion of reworking and confirming an onshore or nearshore

marine environment.

Intertidal, small scale, asymmetrical ripples, climbing ripples

and some symmetrical ripples occur throughout the fine sands. They
indicate tidal ebb and flow conditions towards the north-northeast (020°)
and south-southwest (200°), and deposition by currents with velocities
of about 0.2m/sec. Clay laminations, which separate ripple trains,
dip a few degrees to the north-northeast, which was also the dominant
flow direction (about four times more ripples show this direction than
200°).

To the southwest of Battisford are several isolated outcrops of
similar deposits. Pebble beds containing flint, phosphatic nodules,
shark's teeth and bone are recorded from Hadleigh, Nayland, Boxted,
Mistly, Langham, Stratford, Shelly, Polstead, Rayden, Monks Eleigh,
Thaxted, Sudbury, Stoke-by-Clare and Shalford (Whitaker 1874, 1878,
1885; Reid 1890; Boswell 1927, 1929; Boswell and Double 1922) and pos-
sibly at Rothamstead (Dines and Chatwin 1930). At these localities
pebble beds 0.25m-0.5m thick are usually overlain by unfossiliferous
pale or ferruginous sands with iron bands. However casts of <u>Cardium</u>
<u>angustatum</u>, a fossil known only from the Red Crag, is recorded from
sands at Hadleigh, and <u>Nucella</u> <u>lapillus</u> from Stoke-by-Clare. Reid (1890)
and Boswell (1929) list several species from Sudbury, all of which are
recorded from the Red Crag.

The majority of shell debris is, however, fragmentary and unidenti-
fiable, except for some more resistant calcite forms, such as <u>Pecten</u>,
and undoubtedly the composition of the pebble beds owes much to the
underlying Eocene and Chalk. At Shalford (grid ref. TL 722292) a small
number of worn, abraded and chemically etched foraminifers and some
mollusc debris is present in greenish sands, which underlie the pebble
bed; local iron cemented decalcified sands contain abundant casts of

Mya, Cardium and Mytilus - very similar to parts of the Upper Red Crag.
The possibility and suggestion of reworking is too strong for a Red
Crag age to be automatically assumed for these deposits. The Red Crag
shells may only indicate an age for the source material for fluvio-
glacially reworked sediment.

Summary and Discussion

Although similar, granulometric analyses of the Creeting, Sudbury
and Battisford pebble beds show a marked difference. Cumulative
frequency curves and histograms of mechanical composition from Battisford
are very similar in shape to those from the Westleton Beds recorded by
Hey (1967), and support the assumption of a littoral marine origin.
Cumulative frequency curves and histograms from the Creeting and Sudbury
deposits do not match, and their origin must be questioned; it seems
that reworking is likely, but it is uncertain when or how. The Battis-
ford Sands are also considered to be of littoral marine origin, on
account of the well preserved sedimentary structures and trace fossils.
A precise age, however, cannot be given for these sands, because no
macrofossils are preserved, or were deposited.

Mollusc assemblages from the Creeting and Sudbury deposits do little
to confirm or deny marine or other origins for the beds, largely
because only part (if any) of the original assemblage is still preserved,
and the shells often show signs of considerable wear. The Battisford
fauna does, however, promote a good correlation with the Red Crag.

Finally, the geographic position of the Battisford deposits suggests
a relationship with the Stradbroke trough rather than the Red Crag
basin. Similarly the Sudbury - Lavenham - Monks Eleigh deposits all lie
on a southwesterly extension of the trough axis. Furthermore, dominant

flow directions at Battisford are towards the trough axis and not

towards the Red Crag basin. The strong implication is that the Chalk

ridge separating the Red Crag basin from the Stradbroke trough provided

an effective emergent barrier between the two basins, and littoral

deposits accumulated on its northwest and southeast flanks. Certainly

the Chalk ridge outcrops at greater heights O.D. than the Battisford

Beds at 45m O.D. However, at depth in the Stradbroke trough, from -15m

O.D. to -39m O.D. at Stradbroke Priory, lie pre-Ludhamian sediments,

which may also be correlated with the Red Crag (Beck et al 1972). The

significant difference in heights above and below O.D. for the various

deposits of Red Crag age appears problematical and cannot be readily

accounted for.

GRAVITY MEASUREMENTS IN THE WASH BY THE UNIVERSITY OF EAST ANGLIA

M. SOLA and P. N. CHROSTON*

Introduction

The aeromagnetic map of southern Britain (Institute of Geological Sciences 1965) shows a prominent magnetic anomaly situated over the Wash. The anomaly reaches a peak to peak (positive) amplitude of over 200 gamma and is one of the more distinct individual features in the complex belt of anomalies extending from Central England to North Norfolk. These magnetic anomalies are derived from sources within the sub-Mesozoic floor, and the relationship between the gravity and magnetic anomalies is of considerable geophysical interest. Gravity data for the mainland area has already been compiled by the Institute of Geological Sciences (see Gravity Survey Overlay Sheet No. 12), but the Wash was not included. In view of the prominence of the Wash magnetic anomaly we have extended the land gravity survey to include the Wash, and the method and results of the survey are presented in this note. The gravity measurements were made in 1972 and 1973, and further measurements have subsequently been made by the Institute of Geological Sciences (hereafter referred to as IGS). Our work is part of a programme of geophysical and geological studies of the sub-Mesozoic geology in East Anglia, and a preliminary account has already been published (Chroston and Sola 1974).

Survey method

Access

The gravity measurements were made on sand banks at varying states

* School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ.

of tide. At low tide only the central part of the Wash has no exposed

banks and about two-thirds of the Wash area can be covered satisfactor-

ily with gravity readings. Access to the Wash was provided by the

University research boat "Envoy", a 26 foot launch, and this is equipped

with Decca navigator for position fixing. The meter was taken-ashore

(to the sand banks) by small boat, and readings taken as close to Envoy

as possible. It is believed that sites could be located with an

accuracy of ±20 m assuming no Decca positioning errors.

In using Decca a fixed positioning correction (provided by Decca)

has been made but small variable errors (due to waves reflected back to

earth by the ionosphere) may also be present. These are believed to

be small, but a total positioning error of ±100 m is possible.

Instrumentation

The instrument used was a Worden Gravity Meter No. 180 owned by

the University of East Anglia. The meter had been calibrated between

the IGS   calibration stations at the Cat and Fiddle Inn (near Maccles-

field) and North Rode, and a calibration value of 0.09654 mgal/per dial

division was adopted for the survey.

Base station

The IGS gravity reference station at King's Lynn (Free Bridge) was

inconvenient for the survey and a temporary station was set up by the

Y.H.A. building in King's Lynn close to the quay. Eight connections

were taken between Free Bridge and the Y.H.A. station, and in addition,

the Y.H.A. station was connected to the Norwich, Cromer and Swaffham

gravity reference stations. A detailed description of the Y.H.A. ref-

erence station can be found in Sola (1974).

Data reduction

The Bouguer anomaly for each station was calculated in the usual manner (see e.g. Dobrin 1960). Special points with regard to various corrections are made below.

Drift correction

A linear rate of drift for the meter was assumed and tests showed that the drift was typically 0.02 mgal/hr. Because of the nature of the survey it was not possible to reoccupy the reference station except at the end of a day's work and the time between successive base readings was often 6 hours or so. The maximum drift during a work period was 0.14 mgal, and the minimum 0.05 mgal.

Elevation correction

A detailed, precision, gravity survey normally requires that the elevation of a station is known to an accuracy of better than 0.1 m. In this survey gravity readings were established at or very close to the actual sea level and the height for each station relative to the high water mark was calculated from the Admiralty Tide Tables. After this height had been established it was reduced to Ordnance Datum. This method was checked for accuracy by comparing calculated tidal heights with actual tidal heights as recorded on a tide gauge operated by Binnies and Partners Ltd., who were also working in the Wash. The results of the comparison are shown in Fig. 1, and it can be seen that the maximum difference is 0.5 metres. This error in elevation determination will lead to an error of 0.1 mgal in the calculation of the elevation correction.

An accurate knowledge of rock densities is usually essential to ensure an accurate calculation of the Bouguer and terrain corrections.
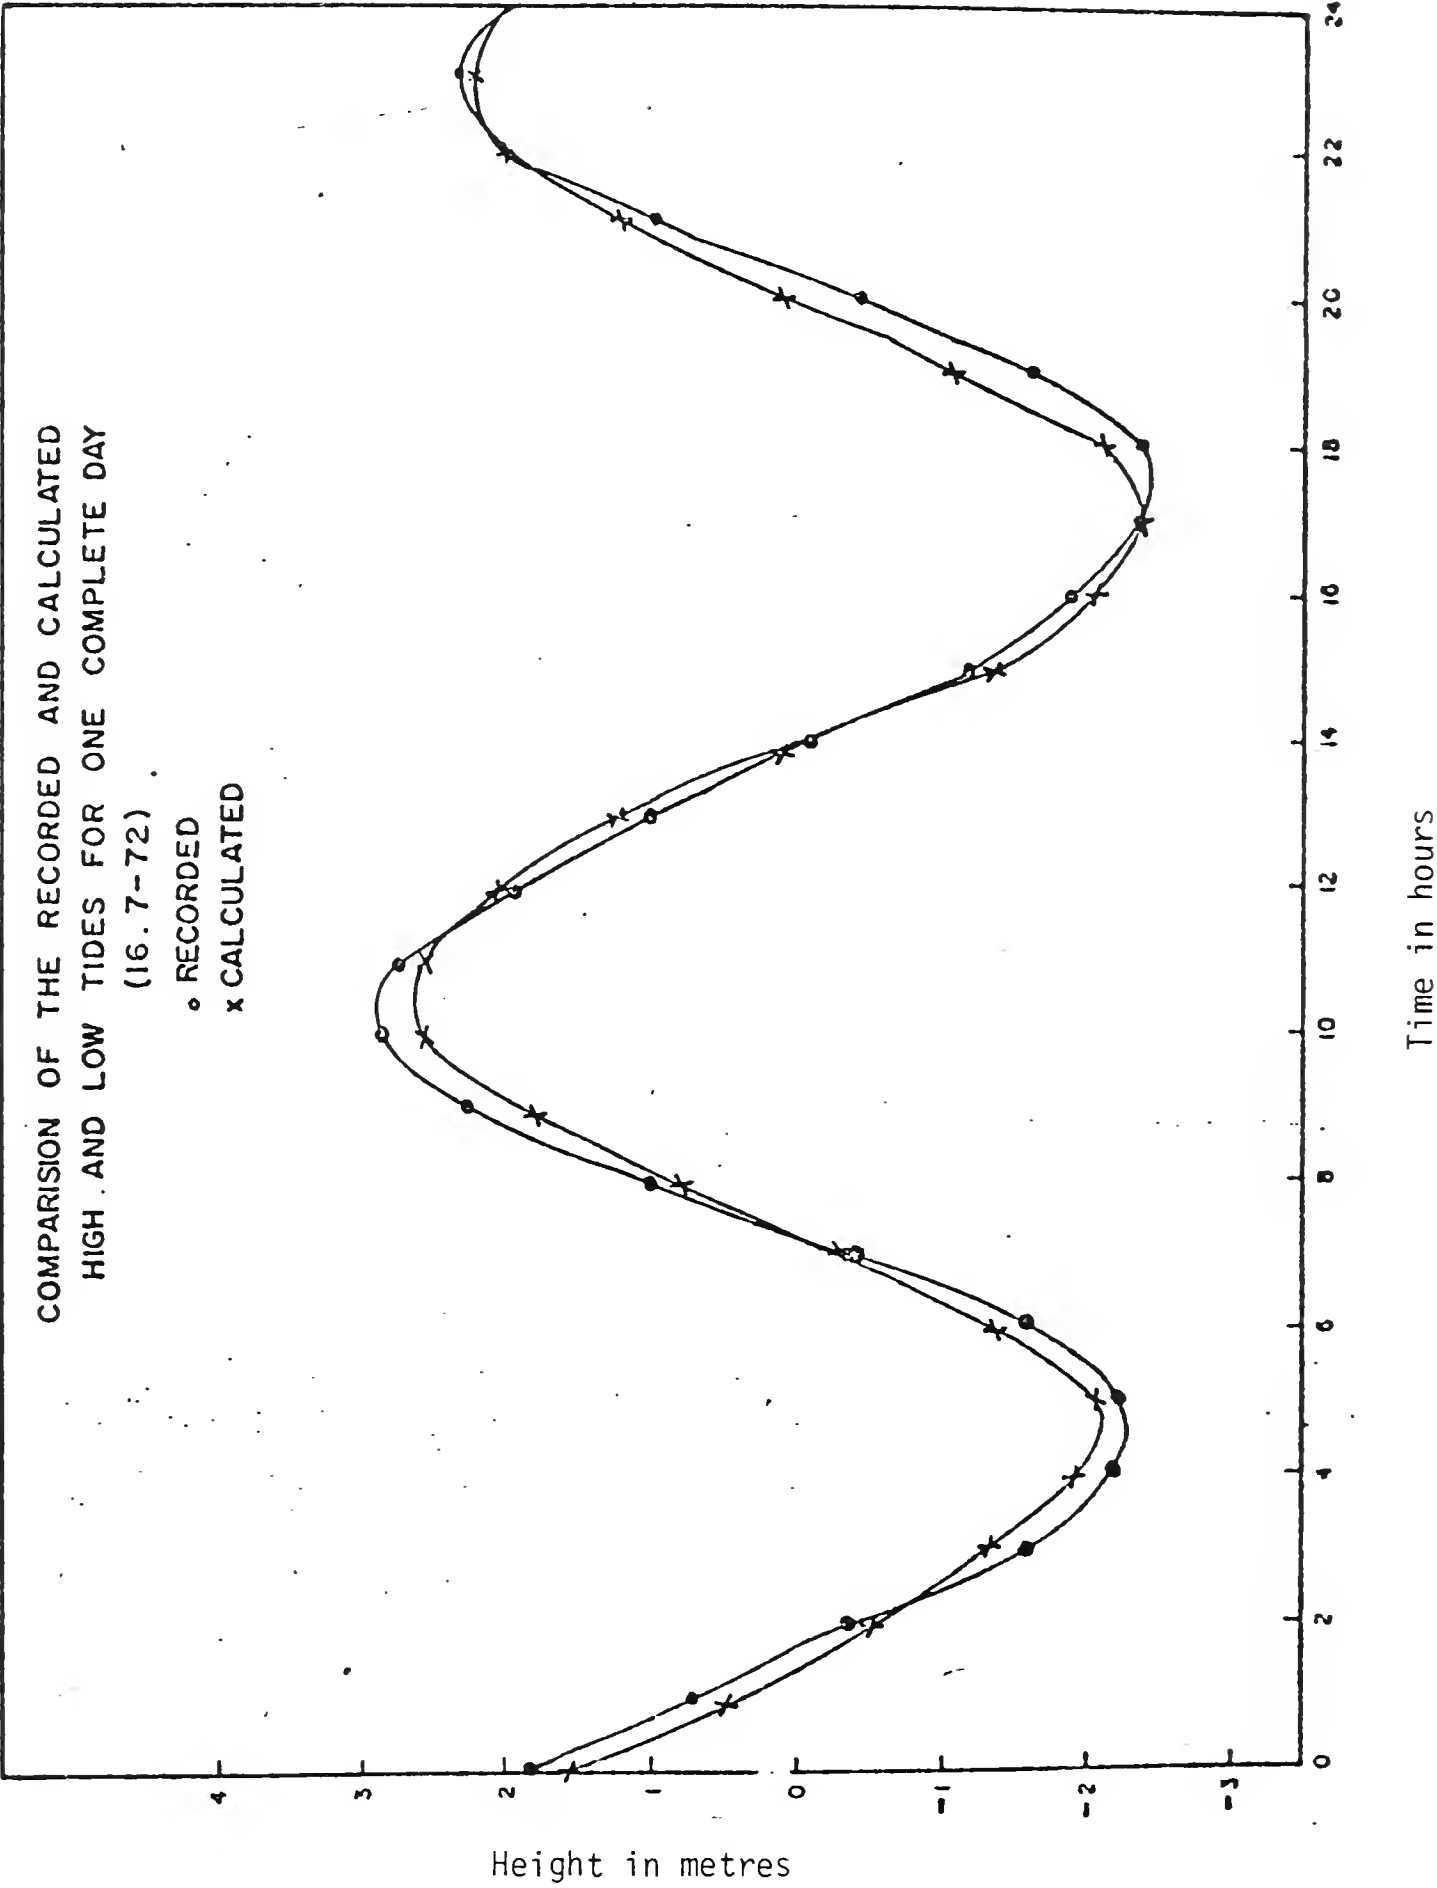

COMPARISION OF THE RECORDED AND CALCULATED
HIGH AND LOW TIDES FOR ONE COMPLETE DAY
(16.7-72)
o RECORDED
x CALCULATED

Height in metres

Time in hours

Fig. 1

In previous work around the Wash, IGS have used values of 1900 -2100 kg m^{-3}, depending on the surface geology. Tables of density measurements given by Jakosky (1950), Dobrin (1960), and others, give densities of 2000 kg m^{-3} for sand, and we have used this value for the reduction density. In fact the maximum difference in elevation between Ordnance Datum and a gravity station is 3.38 metres and hence the combined free-air and Bouguer correction is very small. An error of 10% in choice of density would result in an error of less than 0.01 mgal in the calculation of the Bouguer anomaly.

Terrain correction

Tests showed that it was unnecessary to apply a terrain correction in this area.

Latitude correction

Theoretical gravity for each site was calculated using the International Gravity Formula (see e.g. Dobrin 1960). Latitudes were completed at one minute intervals and the change in gravity assumed to vary linearly between these latitudes. Assuming a positioning error of ±100 m the theoretical latitude could be calculated with an error of less than 0.08 mgal.

Total error in the Bouguer anomaly

Applying the maximum likely errors due to instrumental drift, elevation, and positioning, a RMS error of approximately 0.1 mgal is obtained. The maximum possible error for any station is believed to be ± 0.15 mgal.

Results

Altogether some 122 gravity readings were made in the Wash. Their positions and a contoured map are shown in Fig. 2. It will be seen

BOUGUER GRAVITY MAP
OF THE WASH

o GRAVITY STATIONS

CONTOUR INTERVAL 1 mgal

Fig. 2   Gravity map of the Wash based on University of East Anglia

gravity stations.

that because of the distribution of the sand-banks the central part of the Wash is not covered. The results clearly demonstrate however a central axial high with a residual amplitude of at least 5 mgal which is also closely coincident with the Wash positive magnetic anomaly. The gravity lows at Southgate and Butterwick, both continue prominently into the Wash, only to be truncated by the central high.

A detailed geological interpretation of the Wash magnetic and gravity anomalies is to appear elsewhere. It is believed, however, that the anomalies cannot be easily explained by relief of the sub-Mesozoic floor. A satisfactory interpretation has to incorporate an intrusion within the sub-Mesozoic geology.

MARINE OSTRACODA FROM THE QUATERNARY NAR VALLEY CLAY, WEST NORFOLK

A.R. LORD* and J.E. ROBINSON*

Introduction

In the Nar Valley, west Norfolk a complex of Quaternary sediments includes a marine clay called the Nar Valley Clay, first described as Nar Valley Brickearth (see Rose, 1865). This clay lies or appears to lie between two tills, Lowestoft Till (Anglian) and so-called Gipping Till (Wolstonian); see Turner (1973, p. 14) for discussion. This deposit has been known to contain marine microfossils for over a century and a note listing ostracods and foraminifera was published in 1865 by T.R. Jones. More recently the palynology of the Nar Valley Clay has been studied by Stevens (1960) using material from boreholes located between East Winch and Narford Hall. On the basis of pollen and by means of comparison with then newly described pollen spectra from the Hoxnian interglacial site at Hoxne, Suffolk (West, 1956) a Hoxnian age was assigned to the Nar Valley Clay. In 1971 a number of slides containing calcareous microfossils, collected by Stevens from her borehole samples, were passed to one of us (ARL) by Professor B.M. Funnell for description. No sediment was then available and as the slides contained only a small number of ostracods with foraminifera, microscopic gastropods and lamellibranchs, echinoderm spines and occasional charophyte oogonia the material was put aside for later study. Recently a rich sample has become available, collected from a reservoir site at East Winch (TF690 150) by P.G. Cambridge and passed on by Professor Funnell. Further samples were also collected in the East Winch area in 1975 by

* Department of Geology, University College London, LONDON WC1E 6BT

Mr. H. Evans and given to J.E.R.

In view of the recent resurgence of interest in Quaternary ostra-
cods and foraminifera as a result of work in and around the North Sea,
the available Nar Valley Clay fauna is listed and discussed here.

The Ostracoda

Ostracods are microscopic bivalved crustaceans inhabiting all
acquatic situations; they are particularly useful for environmental
analysis.

The Stevens slides - of nine slides five were found to contain
ostracods:

2.80   Carinocythereis cf. C. antiquata (Baird)

        Leptocythere castanea (Sars)

        Semicytherura cf. S. sella (Sars)

4.80   Elofsonella concinna (Jones)

        Carinocythereis cf. C. antiquata (Baird)

        Leptocythere sp 1.

5.80   Carinocythereis cf. C. antiquata (Baird)

        Elofsonella concinna (Jones)

8.80   Leptocythere pellucida (Baird)

        Semicytherura cf. S. sella (Sars)

        ? Eucytheridea sp. juv.

Unnumbered Slide A

Carinocythereis cf. C. antiquata (Baird)

The numbering on the slides does not appear to correspond with any
borehole or depth mentioned in Steven's paper and the small number of
specimens make this material of little use on its own. It is worth
noting that Jones (1865) recorded the following species, which were

actually described by G.S. Brady in the same year:

Cythere arborescens Brady (= Aurila convexa (Baird))

Cythere aspera Brady (= Carinocythereis antiquata (Baird))

Cytheridea punctillata Brady (= Eucytheridea punctillata (Brady))

Normania carinata Brady (=? Loxoconcha rhomboidea (Fischer))
(actually described as
 Cythere carinata)

The East Winch sample (TF690150) - contained a rich ostracod assemblage

composed of:

Carinocythereis cf. C. antiquata (Baird) (males, females and suite of instars)	342 valves	64.0%
Semicytherura cf. S. sella (Sars) (males, females, instars)	1 carapace 60 valves	11.60%
Leptocythere sp. 1 (adults)	32 valves	5.90%
Leptocythere castanea (Sars) (males, females, instars)	28 valves	5.25%
Hirschmannia tamarindus (Jones) (adults)	1 carapace 25 valves	5.05%
Loxoconcha cf. L. rhomboidea (Fischer) (adults, instars)	1 carapace 16 valves	3.37%
Leptocythere pellucida (Baird) (adults)	15 valves	2.80%
Leptocythere sp. juv.	9 valves	1.70%
Elofsonella concinna (Jones)	1 juvenile valve	0.18%

Total: 3 carapaces, 528 valves

Evans' material from East Winch - two samples were analysed:

i)   Carinocythereis cf. C. antiquata (Baird)   1 carapace,   25 valves
     (males, females and instars)

     Robertsonites tuberculata (Sars)   28 valves
     (males, females and instars)

Elofsonella concinna (Jones)   23 valves
(adulst and instars)

Leptocythere pellucida (Baird   3 valves
(adults)

Hirschmannia cf. H. tamarindus (Jones)   2 valves

Leptocythere sp. 1   1 valve

? Krithe sp.   1 valve

                                Total: 1 carapace, 83 valves

ii) Robertsonites tuberculata (Sars)   17 valves
     (adults and instars)

     Elofsonella concinna (Jones)   15 valves
     (adults and instars)

     Carinocythereis cf. C. antiquata (Baird)   10 valves
     (adults and instars)

     Hirschmannia cf. H. tamarindus (Jones)   5 valves

     Leptocythere sp. 1   3 valves

     Eucytheridea bradii (Norman)   1 valve

                                Total: 51 valves

Discussion

The East Winch sample (TF690150) is rich and the presence of
adults with suites of instars, especially of Carinocythereis indicates
that the assemblage is in-situ and possibly approximates to the original
biocoenosis. The assemblage reflects shallow, warm-water conditions,
but for the presence of such a full group of Carinocythereis which
indicates deeper water conditions of up to 20m. depth. Elofsonella
concinna is a cooler water, more northerly species and although the
presence of a single juvenile valve in the sample from TF690150 is not
particularly significant, the occurrence of this species in larger

numbers in the two other East Winch samples indicates cooler or deeper water conditions. There are substantial differences between the larger East Winch assemblage and the two smaller ones, which contain relatively large numbers of Elofsonella concinna and Robertsonites tuberculata and fewer Carinocythereis.

The available assemblages differ from each other, but also differ from other British Hoxnian marine ostracod material. For example, the fauna from the Bridlington Crag of Dimlington, North Humberside described by Neale and Howe (1975, p. 404) is more diverse and reflects cooler water conditions. The Nar Valley Clay material also differs from Holsteinian assemblages described from north Germany and Denmark. In almost all the species listed here there are subtle differences in morphology between the living species and the Nar Valley Clay material, which may prove useful for correlation purposes.

Of particular interest is the depth significance of the ostracods. The Nar Valley Clay clearly reflects the high sea-level of an inter-glacial optimum, which was substantially higher than present sea-level (cf. the possibly Hoxnian Slindon Sands of Sussex). The faunas imply that the Nar Valley area during the Hoxnian was not simply a shallow embayment of the Wash and that the shoreline was at some distance from the present-day marine limit. We believe that a borehole re-investigation of the Nar Valley Clay is highly desirable for an improved under-standing of the Hoxnian Interglacial in Britain.

Appendix

The following foraminifera were also found in the East Winch
(TF690150) sample:

Ammonia beccarii (Linne)	288	72.0%	size range	0.20-0.87 mm
Elphidium incertum (Williamson)	47	11.7%	size range	0.12-0.50 mm
Elphidium 'clavatum' Cushman	8	2.0%	size range	0.40-0.50 mm
Elphidium williamsoni Haynes	5	1.25%	size range	0.43-0.41 mm
Derived Cretaceous specimens	52	13.0%	size range	< 0.1 mm

Foraminifera were also found in the Steven's slides, but the only
significant differences were the presence of Quinqueloculina seminulum
(Linne) (size 0.43-0.90 mm) and Elphidium macellum (Fichtel and Moll)
(size 0.87-0.56 mm), both of which occur around the British Isles at the
present day but apparently close to their northern limit of occurrence.
The same distributional consideration is applicable to Ammonia beccarii,
the dominant species in the East Winch sample, which lives on the inner
shelf, estuaries and also lagoons of less than normal marine salinity.
The preponderance of this one species A. beccarii suggests reduced sal-
inity and the presence of Quinqueloculina seminulum, which has little
tolerance for salinity variation is probably not significant.

SECRETARY'S REPORT FOR 1977

There were five lecture meetings which together with the A.G.M, made six indoor meetings held during the year. They were: January, Mr P. G. Cambridge, 'Marine Deposits in the Southern North Sea in Neogene and Holocene Times, with Particular Reference to the Crag of East Anglia'; February, Mr R. Gallois, 'The Pleistocene History of West Norfolk'; March, a joint presentation by Professor B. M, Funnell and Mr N. B. Peake on 'Some Mineral Resources of Norfolk'; October, Mr P. G. Cambridge, 'The Geology of Malta'; November, Mr R. Toynton, 'Underground Water in the Norfolk Chalk - Is it all it's Cracked up to be?'; and December the Annual General Meeting.

The Meetings of February and October were held at the Norfolk College of Arts and Technology, Kings Lynn in accordance with the Society's aim to provide one meeting in each winter's programme at Kings Lynn.

Following the canvassing of members' opinion it was agreed to return to the Castle Museum, Norwich as the venue for meetings, and thanks are due to Mr Peter Lawrence and Mr Brian McWilliams for making this possible. Although meetings at the University were well attended members had expressed a preference for a more central location. It is probable that some meetings will be held at the University in future but the normal venue from now on will be at the Castle.

There were three committee meetings held during the year.

The last year has been a difficult one for me personally and it has meant that I had to rely a great deal on the support of the Committee. In particular I should like to express my thanks to Philip Cambridge who has taken a lot of the load from my shoulders for example, in print-ing the programme and sending it out to members. He also distributed

120

the Bulletin and prepared the agenda for the A.G.M. Thanks are also

due to Dr Neil Chroston for stepping into the position of Editor and

succeeding in publishing a Bulletin this year, when at one time it

looked rather doubtful that one would appear at all.

This year's Committee is as follows:

Secretary	Dr C. J. Aslin
Treasurer	Mr P. G. Cambridge
Editor	Dr P. N. Chroston
Field Meeting Secretary	Mr P. J. Lawrence
Committee Members	Mr N. E. Dean
	Mrs E. Evans
	Mr N. B. Peake

December 1977   Christopher J. Aslin

CONTENTS

The Geological Society of Norfolk exists to promote the study and knowledge of geology, particularly in East Anglia, and holds monthly meetings throughout the year. Visitors are welcome to attend the meetings and may apply for membership of the Society. For further details write to the Secretary: Dr. C.J. Aslin, University Library, University of East Anglia, Norwich NR4 7TJ.

Copies of this Bulletin may be obtained from the Secretary at the address given above.

The illustration on the front cover is from Figure 80 (page 468) of the second edition of H.B. Woodward's "The Geology of England and Wales", published by G. Philip & Son, London in 1887. It is after a photograph of a Chalk pit at Whitlingham, near Norwich. The beds above the Chalk with flints, seen best to the right of the picture, comprise 4.5 to 6 m of Norwich Crag Series, made up from bottom to top of: Stone bed; False-bedded sand and gravel, with shells; Impersistent laminate clay, and shelly seam; and Pebbly gravel and sand, with seam of shells.

PALAEOENVIRONMENTAL ANALYSIS OF THE DOBB's PLANTATION SECTION, CROSTWICK (AND COMPARISON WITH TYPE LOCALITIES OF THE NORWICH AND WEYBOURNE CRAGS).

B.M. FUNNELL[*]

Introduction

This section was excavated by the Geological Society of Norfolk and the Ipswich Geological Group in September 1977 (Cambridge 1978a), and a preliminary account of the section and the molluscs recovered was given by Cambridge (1978b). Foraminifers were examined from the same samples from which the molluscs were obtained. The results of the examination of the foraminifers are here combined with a re-assessment of the mollusc data in order to interpret the environment in which these shelly sands accumulated.

Foraminifers

Foraminifers were examined from six samples. In view of the fact that they were dispersed in a large amount of mineral sand of the same size range, they were concentrated by flotation on carbon tetrachloride liquid. Only the 500 to 250μ m size fraction was analysed. (This size fraction has been consistently used by the present author for comparative work on Crag foraminifers.) The results are shown in Table 1, and illustrations of some of the most abundant species are given in Figure 1. Altogether 19 species were identified. The Arabic sample numbers in the Table correspond to the Roman numerals used in the section drawn by P.G. Cambridge (1978b, p. 82).

Sample 1, at 0.10m above the Chalk, is dominated by Elphidiella hannai, a Pacific species occurring on the west coast of North America at the present day, but very common in the North Sea in the early Pleistocene. It is followed in abundance by Cibicides lobatulus, a warm temperate to boreal or even arctic species commonly found attached to seaweed, and Ammonia beccarii a temperate intertidal or shallow sub-tidal species not present off the coasts of the British Isles during glacial periods. Several species of Elphidium are also present.

TABLE 1.   Foraminifera from Dobb's Plantation
(CCl$_4$ float; 500-250μm fraction only; 0 = less than 1%)

At 0.40m above the Chalk sample 2 contains an even higher percentage
of E. hannai, a lot of Elphidium frigidum a boreal to arctic species, some
Elphidium orbiculare another boreal to arctic species, not found south of
the Faeroes at the present-day, no A. beccarii and few Cibicides lobatulus.
Significantly cooler water conditions are indicated.

Samples 4, 6 and 7, between 0.65 and 0.70m above the Chalk are all
(not unexpectedly) very similar. All contain over 80% of E. hannai, several
percent of Elphidium pseudolessonii (like the basal sample 1) and a few
percent of A. beccarii, and E. frigidum. They also contain the intertidal

Figure 1. Dobb's Plantation Foraminifers.

1-3 Ammonia beccarii, 4-5 Elphidiella hannai,
6-8 Cibicides lobatulus, 9-10 Elphidium pseudolessonii,
11-12 Elphidium frigidum.

(All specimens are about 0.5mm in diameter; drawn from actual
specimens obtained from Dobb's Plantation; all except
E. frigidum from sample 1, E. frigidum from sample 2.)

species _Elphidium williamsoni_. Apart from the presence of this last-named species and the consistently high percentage of _E. hannai_ these samples look rather like a mixture of samples 1 and 2.

Finally sample 8, 1.25m above the Chalk, contains 94% _E. hannai_ accompanied by _C. lobatulus_, _E. pseudolessonii_, and single examples of six other species.

Briefly this sequence of foraminiferal assemblages looks like an intertidal or shallow sub-tidal, temperate, open coast assemblage at the bottom, and a boreal, increasingly cold intertidal or shallow sub-tidal assemblage from 0.40 to 1.25m above the Chalk. Re-worked temperate specimens may well contribute to the higher assemblages particularly at 0.65 to 0.70m.

Molluscs

The molluscan faunas throughout the section (Cambridge 1978b) consistently include intertidal species. Two of these, _Mytilus edulis_ and _Littorina littorea_ are commonly considered rocky shore species, but in fact are quite at home at the present day on stable muddy or sandy shores with scattered stones,as well as on exposed chalk or flint. Both environments could be expected in the vicinity of the accumulating Crag at Dobb's Plantation. The infaunal intertidal species at Dobb's Plantation, found at the present day on sandy shores containing variable quantities of mud are _Cerastoderma edule_, _Mya arenaria_ and _Scrobicularia plana_. _Macoma balthica_ is present in the top sample only.

Sublittoral species are also present. Forms such as _Hiatella arctica_ and _Venus fasciata_, which frequent sublittoral shell gravels, are commonest in the lower part of the section, (0.10-0.65m), where the section is indeed more shelly. The sublittoral muddy sand inhabitant

Astarte (_Tridonta_) _montagui_ occurs in all except the highest sample,

but is only accompanied by other sublittoral muddy sand species,

Phacoides (_Lucinoma_) _borealis_, _Nucula_ _nucleus_ and _Turritella_ _communis_

in the middle (0.65-0.70m) of the section. The sublittoral silt-

tolerant _Arctica_ _islandica_ occurs throughout. The sublittoral boreal

species _Neptunea_ _antiqua_ occurs only in the highest (1.25m) sample,

and the sublittoral motile form _Chlamys_ _opercularis_ occurs only in

the lowest (0.10m) sample.

Overall, allowing for the relative total numbers obtained from

each sample (sample 2 is the least rich) and the probabl persistence

of more robust species (e.g. _A._ _montagui_) furthest from source, the

general succession of facies at Dobb's Plantation, based on the molluscs

found, is:

(a) immediately post-transgressive deposit incorporating intertidal,

sublittoral and remanié fossils, with shell-gravel concentrates, areas

of bare Chalk and overall evidence of tendency to removal of finer

sediment fraction both from accumulating sediment and possibly also

from offshore zone. (Samples 1 & 2, 0.10 to 0.40m). It is inferred that

the water was shallow and wave and current action effective .

(b) about half-way up the section at around sample 4 (0.65m) there is an

influx of sublittoral muddy sand species, which might be taken to be an

indication of deepening water, either locally or offshore, but this level

also includes some large relatively unworn flints, so this could be simply

an indication of increasing storminess bringing in both offshore shells

and seaweed holdfasts.

(c) the upper part of the section (0.70m upwards) is characterised by

loss of the shell gravel species, dominance of sands with shells and

some medium gravel, and finally introduction of Macoma balthica and the boreal species Neptunea antiqua.

Comparison with Bramerton and Wroxham sections

Only mollusc listings are available from Wroxham for comparison; both foraminifers and molluscs have been investigated from Bramerton (for details see Funnell, Norton & West 1979).

At Wroxham Hall pit (TG 272160) a sample from 0.38-0.61m above the Chalk contained: Mytilus edulis, Macoma sp., Mya arenaria, Hiatella arctica and Yoldia sp., all of which are common throughout the Dobb's Plantation section (although most of the H. arctica found there did not occur more than 0.65m above the Chalk). A sandy and perhaps rocky inter- tidal zone, together with a silty, muddy and possibly shell gravel or stony sub-littoral, are indicated.

At 1.30-1.50m the Wroxham deposit includes: Cerastoderma edule, Macoma sp., Corbula gibba, Donax vittatus, Macoma obliqua and Mya arenaria. Again all of these are present throughout the Dobb's Plantation section and the environmental indications are little changed from those of the lower Wroxham sample.

No Macoma balthica was found at Wroxham Hall. All in all it seems unlikely that there is any significant difference between the Wroxham Hall and Dobb's Plantation mollusc assemblages except that the number of shells collected at Dobb's Plantation was larger.

Comparisons with the Bramerton sections are more complicated. The newly identified Alnus- Quercus- Carpinus pollen assemblage bio zone constituting the BRAMERTONIAN stage extends from the base of the Blake's Pit section to 4.00m above the Chalk. The most abundant molluscs in this stage in Blake's pit are: Abra alba, followed by Mytilus edulis, Cerastoderma edule, Littorina littorea, Calyptraea chinensis, Hiatella arctica, Macoma praetenuis, Macoma sp., Spisula sp. and Yoldia sp.

Apart from the abundance of Abra alba and the presence of Calyptraea chinensis these are all species found in the Dobb's Plantation section.

In the correlative levels in the Bramerton Common section, up to at least 3.10m above the Chalk on the basis of the foraminifers, the molluscs are again dominated by Abra alba in the lower part of the sequence, followed by Calyptraea chinensis, Hydrobia ulvae, Mytilus edulis, Littorina littorea and Hiatella arctica. In the upper part of the sequence Hydrobia ulvae dominates followed by Cerastoderma edule, Macoma sp., Littorina littorea, Nucella lapillus and Cylichna alba. There is more evidence here of sub-littoral and perhaps brackish water forms than in either the adjacent Blake's pit section or the Dobb's Plantation section.

As regards foraminifers the sample from the Bramertonian of the Blake's Pit section contains Elphidiella hannai (47%), Ammonia beccarii (14%), Elphidium pseudolessonii (11%) and lesser percentages of Cibicides lobatulus, Cibicides pseudoungerianus and Cibicides subhaidingerii . The 0.10m above the Chalk level at Bramerton Common is very similar containing the same species in almost indentical rank order of abundance. In both cases the species of Cibicides other than C. lobatulus may be derived. Samples from 0.05 and 1.60m above the Chalk at Bramerton Common are less prolific but still contain E. hannai, A. beccarii, E. pseudolessonii and C. lobatulus as consistent components. All these Bramerton samples are very similar to the lowest Dobb's Plantation sample, which again contains E. hannai (55%), followed by A. beccarii, E. pseudolessonii and C. lobatulus.

The Pinus-Ericales-Gramineae pollen assemblage bio zone, which is thoug to represent the Pre-Pastonian a stage, is found at Blake's Pit, Bramerton at 5.30m above the Chalk. At 4.95 to 5.00m,above the Chalk the molluscs consist of Hydrobia ulvae (63%) followed by Cerastoderma edule,Macoma sp.,

Littorina littorea, Nucella lapillus and Valvata piscinalis. There is little
to distinguish this from the molluscan assemblage found at 2.50m above the
Chalk in the Bramerton Common section.

However the foraminifers at 4.95 to 5.00m in the Blake's Pit section
show E. hannai (56%) and E. pseudolessonii (20%) dominating the fauna with
reduced representation of A. beccarii and C. lobatulus and significant
representation of Elphidium frigidum such as characterises the 4.60 to 6.10m
levels on Bramerton Common. Elphidium orbiculare is also present.

The molluscs at a comparable level, actually at 6.50m above the Chalk
on Bramerton Common (ie. at the base of the upper shell bed there) include
Macoma sp., Cerastoderma edule, Macoma calcarea, Macoma obliqua, Macoma
obliqua, Macoma praetenius, Mya arenaria, Spisula subtruncata.
Hiatella arctica, Mytilus edulis and other species.

Both the foraminifers (at 4.95 to 5.00m Blake's and at 4.60 to 6.10m
Bramerton Common) and the molluscs (mainly at 6.50m Bramerton Common) show
considerable similarity to the Dobb's Plantation samples at 0.65 to 0.70m
above the Chalk. This is also probably the most likely level at Dobb's
Plantation to which both the Wroxham Hall samples relate. Tentatively
therefore it seems likely that the higher part of Blake's Pit (above 4.95m),
the middle part of Bramerton Common Pit (4.60 to 6.50m at least), the middle
part of Dobb's Plantation (around 0.65 - 0.70m) and possibly all the Wroxham
Hall locality (0.38-1.50m) fall in the earlier part of the pre-Pastonian a
stage.

The highest level at Dobb's Plantation (1.25m above the Chalk) shows
a mollusc fauna in which Arctica islandica, Cerastoderma edule, Mya arenaria,
Mytilus edulis, and Littorina littorea continue to be important. but are now
joined by Macoma balthica. The foraminifers at this level are totally
dominated by Elphidiella hannai(94%), the only other species present being

C. lobatulus, E. pseudolessonii, E. frigidum, E. orbiculare and a few

others, some of which may be derived. A very similar picture emerges at

10.60m above the Chalk at Bramerton Common where there are no molluscs, but

the foraminifers comprise E. hannai (90%), E. pseudolessonii,C. lobatulus,

E. frigidum and a few other species including Quinqueloculina seminulum

Buccella frigida and Buccella inusitata. This Bramerton Common sample is in

its turn very similar to samples taken from the Weybourne Crag at 0.05 to

3.00m above the Chalk at Sidestrand (Funnell 1961a,b). These sediments also

contain Macoma balthica (Norton 1967), and West (1979) has recently also

allocated them to the pre-Pastonian a stage. The introduction of Macoma

balthica into the southern North Sea, and the rise of E. hannai to 90%

dominance (with A.beccarii absent) seems likely to have occurred a little

way into the pre-Pastonian a cold stage.

Conclusion

None of these suggested correlations is surprising. They are very much

in line with the conclusions of nineteenth century geologists, such as Harmer,

Wood Jnr and Woodward. There does seem to be a transition from warmer to cooler

conditions in the Bramerton sections. It does seem that this culminated in the

Wroxham area in the introduction of Macoma balthica, and it appears that this

level is to be correlated with the Weybourne Crag of the North Norfolk coast.

Even the transgression which brought the Weybourne Crag sea over virgin Chalk

seems to be reflected in a change from mainly littoral to sublittoral (Macoma-

dominated) conditions in the Bramerton sections. The interesting thing is that

the quantitative re-study of molluscs and the quantitative and microscopic study

of foraminifers and pollen (both methods largely unavailable to the nineteenth

century geologist), combine together to confirm earlier workers' conclusions.

PRELIMINARY HOLOCENE STRATIGRAPHY OF BRANCASTER MARSHES

P. MURPHY* AND B. M. FUNNELL+

Introduction

Although the accretional coastal environment of North Norfolk has long
since been the subject of study by naturalists and physical geographers
(Steers 1960), no serious attempt ever seems to have been made to determine
the stratigraphy of the Holocene intertidal sediment prism. Mainly in the
hope of learning something of past conditions seaward of the Roman fort at
Brancaster we sank 13 Hiller auger holes in the summer of 1978 and repeated
one of these to a depth of 8 m with a Minuteman auger in September 1978.
The position of the line of auger holes in relation to the fort at Brancaster
is shown in Figure 1. Our interpretation of the section revealed is given
in Figure 2.

Samples recovered from the Hiller auger holes have been examined for
molluscs, foraminifers and plant macrofossils.

The General Nature of the Sediments

Apart from a reed-bed near the landward end of the section the surface is a
late Aster marsh at 2.84 to 3.00 m O.D. and is probably at a level between Mean
High Water Neaps and Mean High Water Springs. It is underlain by less than
0.5 to almost 3.0 m of intertidal MUD. Beneath the reed-bed, in auger holes
2, 3 and 4 Phragmites rhizomes are present. In auger holes 8 and 9 either side
of the main creek Hydrobia (Peringia) ulvae, Scrobicularia plana and Littorina
sp. were found towards the base of the mud. The mud is underlain by sand in
all the auger holes, but a thin peat intervenes between the mud and the sand
in holes 5,7 and 8. The mud contains numerous foraminifers.

+ School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ.
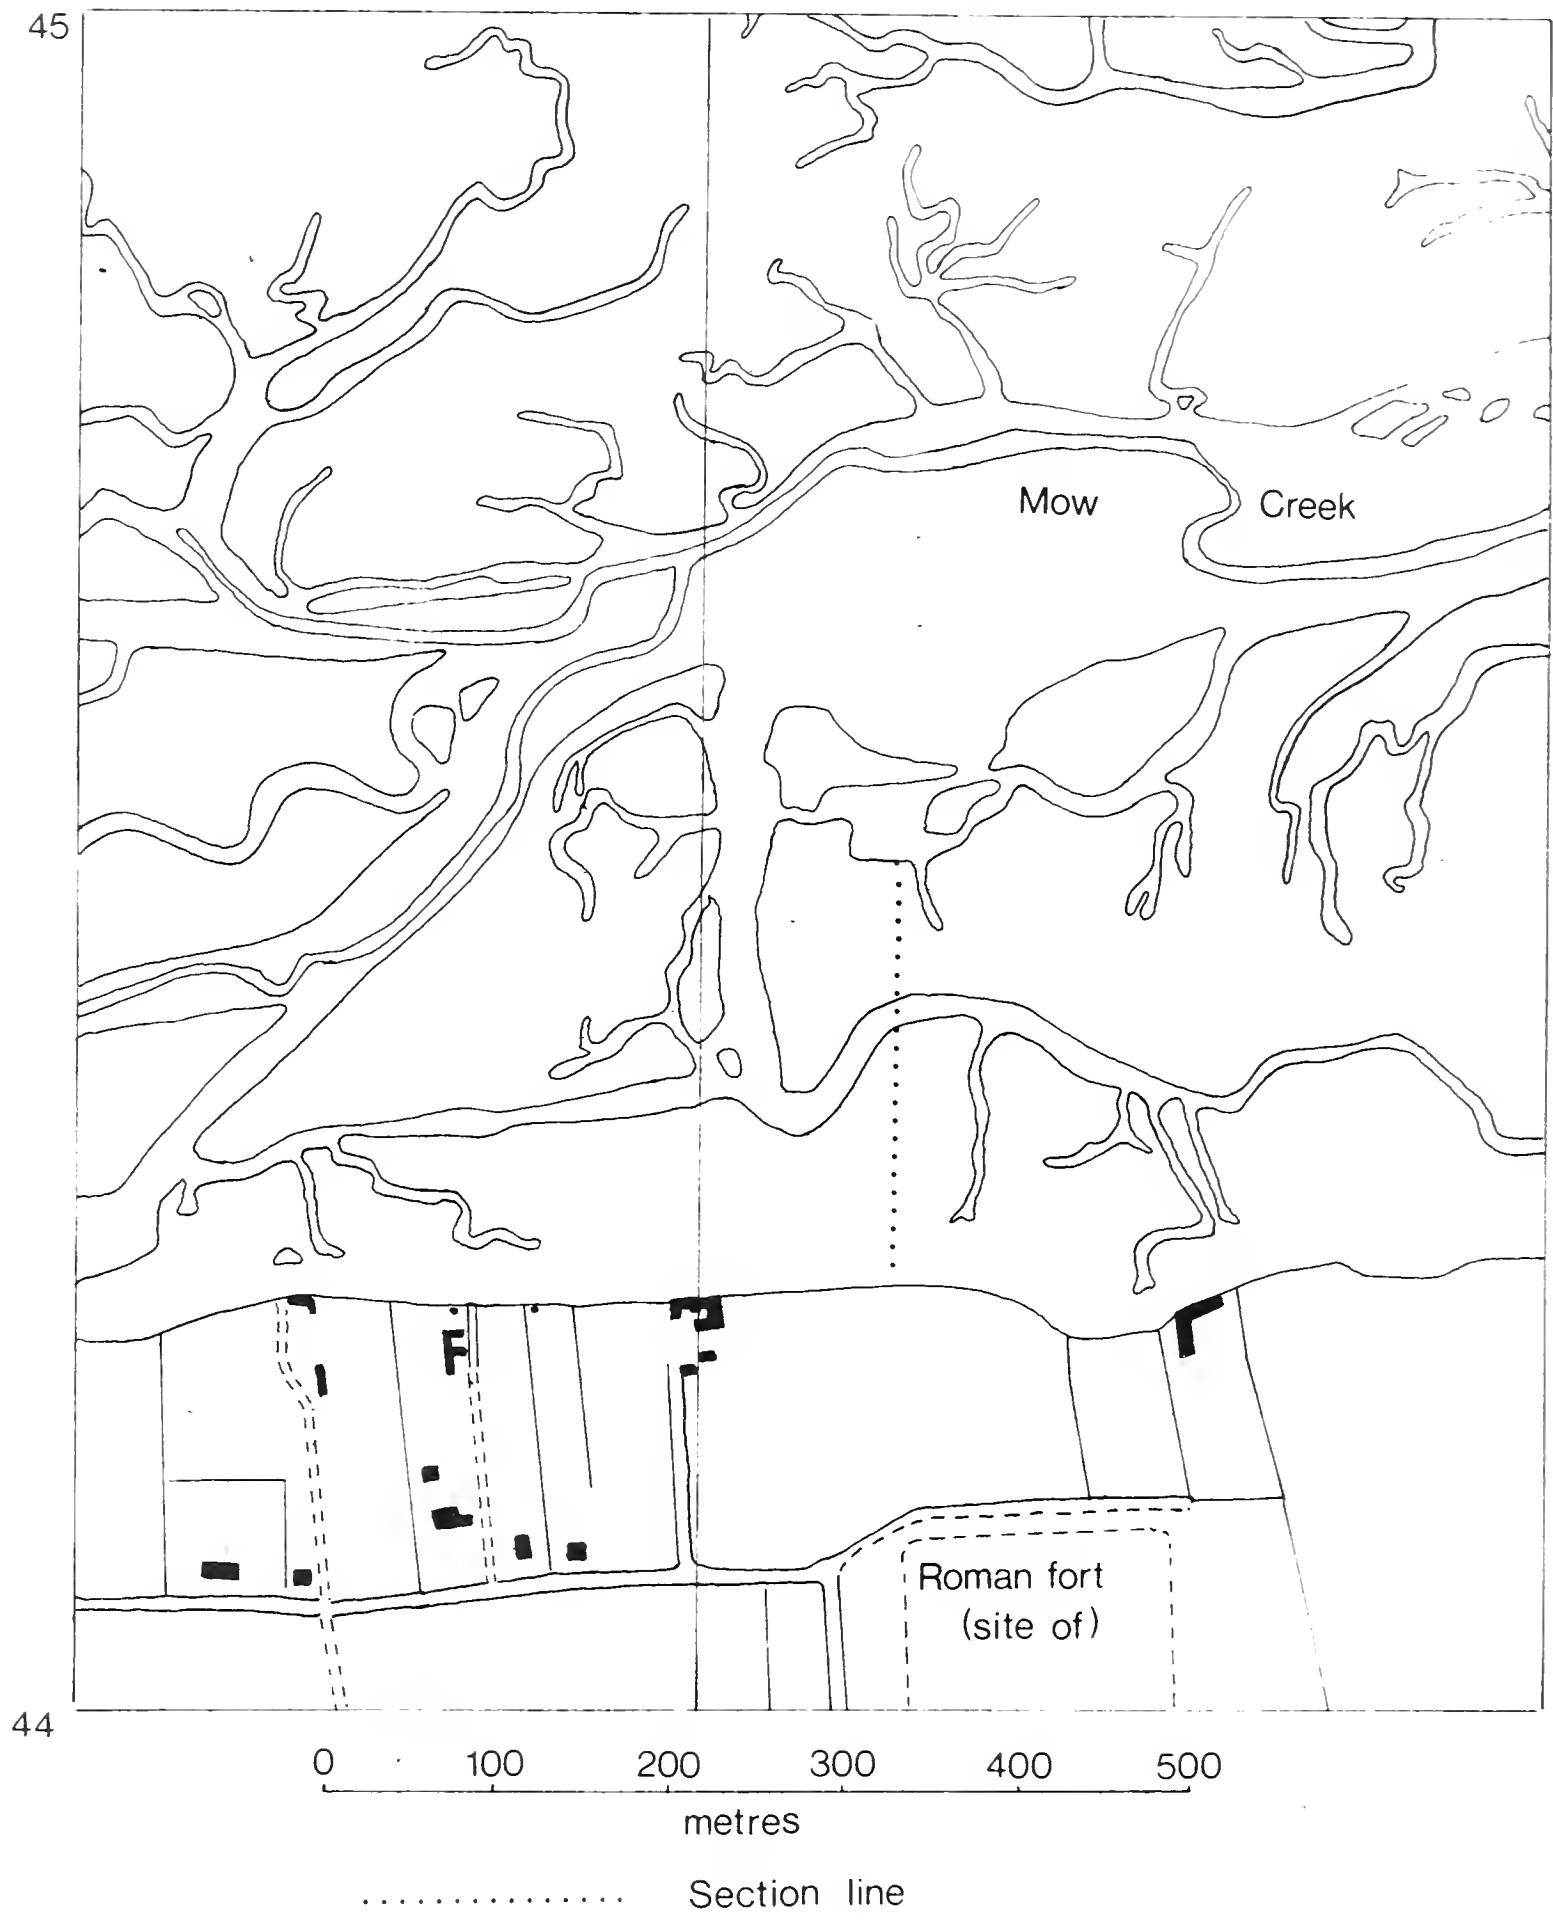

Figure 1   Relation of section through Holocene marsh sediments to
position of Roman fort at Brancaster.

The PEAT itself is never more than 0.5 m thick and rests on sand between -0.34 and 0.39 m O.D. It is a brushwood peat and in hole 7 it contained remains of Alnus glutinosa. It is like the Judy Hard peat (Godwin and Godwin 1960, p. 74) in resting on sand but lies at a higher level relative to O.D. (-0.25 to 0.75 m O.D. compared with -3.00 to -0.40 m). Nevertheless it could still be of the same or slightly later age. The Judy Hard peat covers the transition from Boreal to early Atlantic. The later Harbour Channel, Lower Golf Club and Upper Golf Club peats (Godwin and Godwin ibid.) either rest on intertidal clays, or, in the case of the last-named, if resting on sand are covered by dune sand.

The SAND, on which the peats or muds rest, and which are impenetrable with the Hiller auger, are interpreted by us as being of two types. The first, we speculate, underlies the mud of holes 9 to 13. It appears to us that this sand is likely to be part of a small spit or barrier beach rolled shorewards possibly over pre-existing peat and intertidal mud. It is partly the form of the top surface of the sand which suggests this to us. It lies roughly between 0.50 and 2.50 m O.D. Also a sample of sand obtained from the bottom of auger hole 9 contained Ostrea edulis and Cerastoderma sp., both common on the spit and bar sands locally, and yielded specimens of the foraminifers Ammonia beccarii and Elphidium williamsoni which are character-istic of the open coast. The sand in which the auger holes terminated land-ward we interpret differently. In places it is overlain by peat (in holes 5, 7 and 8) and its surface declines regularly at 1 in 6, from 2.75 m landward to -0.25 m O.D. seaward at hole 8. This could be a beach profile, but if the peat overlying it is of early Atlantic age it would pre-date the local Flandrian transgression, a Holocene marine origin would be ruled out and a soliflucted periglacial or glacial origin could be possible. This sand is over 5 m thick

Murphy and Funnell

Brancaster Marsh Sediments

Marsh mud

Peat
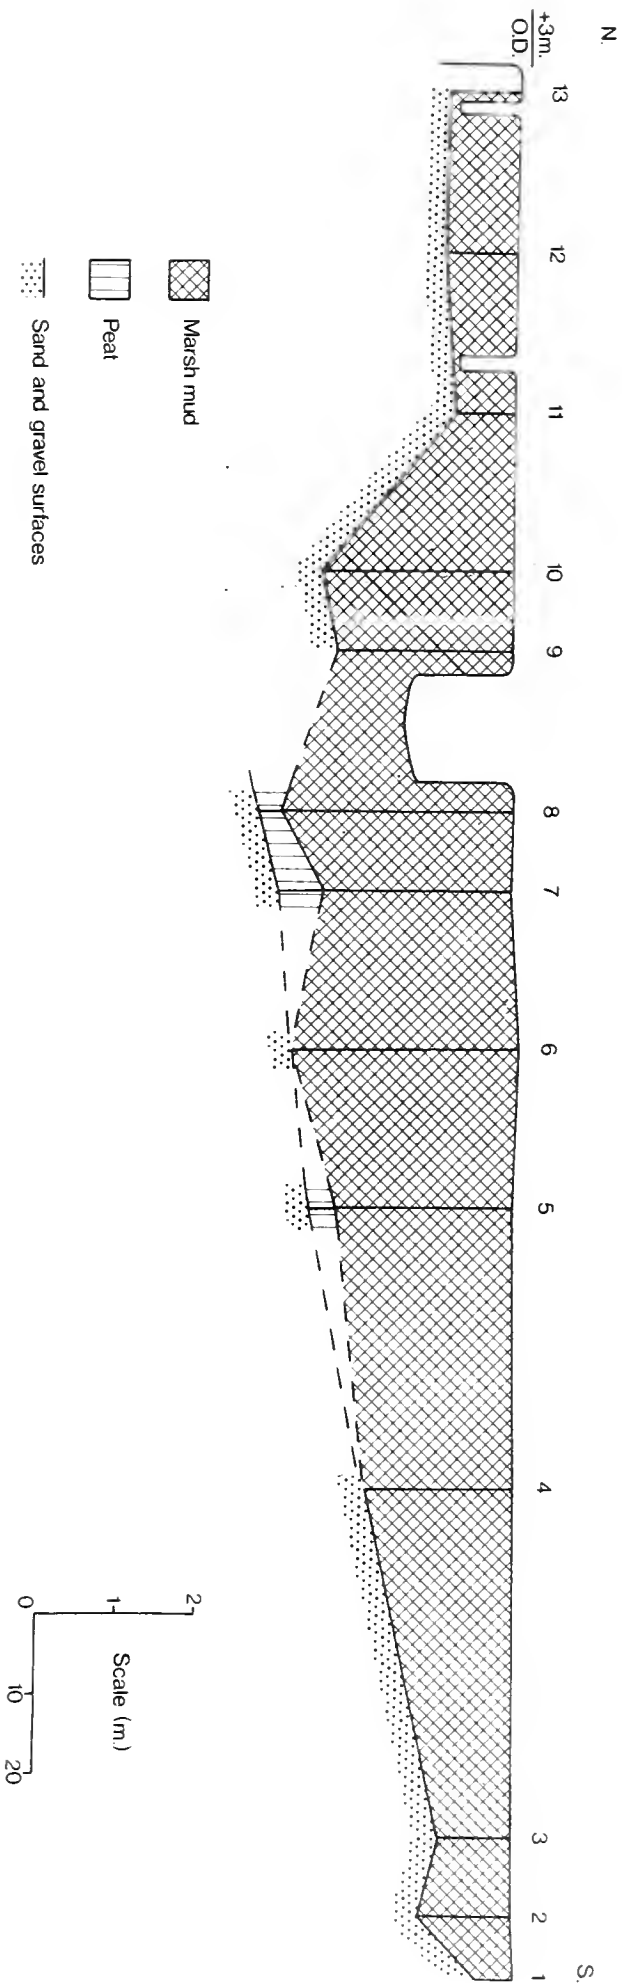

Sand and gravel surfaces

Scale (m)

Figure 2   Section through Brancaster marsh sediments

at hole 5, where the Minuteman auger appears to have just reached CHALK at 8 m below surface. Erosion of chalk to -5 m O.D. at this point seems unlikely to have been achieved by marine erosion during the Holocene, but could have been achieved by marine erosion during the Last Interglacial (Ipswichian) - see General Conclusions.

Foraminifera

Arenaceous salt marsh foraminifers were found throughout the intertidal mud of auger holes 5 and 12. Two species dominate the assemblages present, and earlier hopes of estimating past tidal levels from the composition of the assemblages have not been realised during this preliminary investigation. The two species mainly represented are Trochammina inflata and Jadammina macrescens. Jadammina is more common at depth in the mud, Trochammina in the upper part (see Table 1). The ratio probably changes with tidal level but no significant changes in sea-level can however be inferred during the period of mud accumulation.

Table 1: Foraminifera from Holocene mud

		Hole No.		
Depth in cm		12		5
	Total No.	% Trochammina	Total No.	% Trochammina
0 - 30	250	48	84*	90
30 - 60	122	79	22	91
60 - 90	172	13	21	71
90 - 120	-	-	9	89
120 - 150	-	-	46	30
150 - 180	-	-	44	16
180 - 210	-	-	-	-
210 - 220	-	-	9	11

* Elphidium williamsoni and Ammonia sp. also present.

General Conclusions

The striking feature of the sedimentary profile obtained seaward of the Roman fort is that it does not indicate any great depth of water before the marsh muds accumulated. At their maximum they only extend down to c. 0.0 m O.D. (i.e. about 0.3 m below mean tide level), and often their base is much higher than this. Immediately north of the fort, peat and sand would have been exposed on the shore between tides before the mud began to accumulate, and the water would only have been 3.0 m deep at MHWS, say 1.8 m deep at MHWN. Deeper water could have existed further seaward (beyond auger hole 8) prior to the emplacement of the sand bank inferred beneath holes 9 to 13.

If the interpretation of the sand surface beneath the mud and peat from hole 1 to 8 as possibly soliflucted and certainly not of marine origin is correct, it could imply that active wave erosion has never occurred at the landward edge of the marsh during the Holocene. The cutting of the old cliff-line which is observed along this coast would then have to be a Last Interglacial (Ipswichian) phenomenon, which might account for its degraded appearance, if it has survived the periglacial conditions of the Last Glaciation.

AGE AND CORRELATION OF PLEISTOCENE DEPOSITS IN WEST NORFOLK

ALLAN STRAW *

Abstract

Previous workers have described two types of older glacial till in west Norfolk, differentiated in composition and colour, and by the nature of their contacts in section. Gallois (1978) showed that at low levels the tills survive along valley lines. This situation is compared with that in south-west Lincolnshire, west of the Fens. Further comparison with central and east Lincolnshire situations supports a case that the two tills were emplaced contemporaneously by two confluent ice sheets. A Wolstonian age for the tills is argued on several grounds, and the former correlation of the darker 'Jurassic' till of west Norfolk with the Anglian Lowestoft Till is rebutted. Various non-glacial Pleistocene deposits, including the Nar Valley Beds, are examined as probable Ipswichian or Early Devensian sediments, together with implications regarding sea-levels about the close of the Ipswichian stage.

Introduction

In terms of the glacial history of East Anglia, the tills of west Norfolk have always had a significance beyond the region itself, at least since Baden-Powell's paper in 1948. This arises mainly from the occurrence of a Chalky-Jurassic till which because of its colour and lithology has usually been correlated with the Lowestoft Till of eastern East Anglia. This particular correlation has raised such difficulties in Pleistocene stratigraphy that Gallois, in his recent Presidential Address (1978) was no doubt wise to avoid it, and his criticism of the British Standard Stages (Mitchell et al, 1973) would seem to be well founded. This paper comments on Gallois' interesting survey of west Norfolk, and discusses problems concerning the age and extra-regional relationships of the tills and associated deposits.

*Department of Geography, Amory Building, Rennes Drive, Exeter, EX4 4RJ.

Character of the tills

Gallois described a dark Chalky-Jurassic till in some detail, stressed the Cretaceous and Upper Jurassic components and argued for derivation from the north-west, specifically the central vale of Lincolnshire. He noted also a paler, grey calcareous till rich in chalk and flint erratics though he did not suggest for this any direction of ice movement. Both tills have been exposed in the sand quarries at Bawsey (TF 679193) for many years and were examined by the author in the early 1960s. In a number of places the dark till consisted primarily of disordered Upper Jurassic clay though many large undigested masses of Kimmeridge Clay up to 2m across were seen, still retaining their original bedding. Some chalk and sandstone fragments, nodular flints and Jurassic limestones comprised other erratics. The intensely chalky till, of a light olive-brown colour, contained not only boulders of chalk but also many 'milled-out' inclusions forming irregular lenses, and much fresh dark grey flint. Rare erratics included small dolerite, sandstone, limestone and quartzite pebbles. Generally the dark Jurassic till rested sharply though in places irregularly on the Sandringham Sands, with the chalky till superincumbent but not forming a continuous cover. In numerous sections the two tills were intermixed, usually in the manner of irregular lenses and inclusions of the Jurassic till in the base of the chalky till. In places, small masses of chalky material occurred in the Jurassic till, but these could have been crushed and sheared erratics of chalk rather than till inclusions. Everywhere the actual contacts between the two tills were sharp and unweathered, suggesting they had been deposited contemporaneously even though the parent ice masses had crossed rather different outcrops. The composite till mass reached a maximum thickness of over 8m, but was restricted to the eastern half of the Bawsey quarry, lying in a broad hollow that appeared to trend north-north-west across the Bawsey spur.

Both tills have been described in greater detail by Evans (1975). He too noted sharp and irregular contacts, and showed by particle-size analysis that in spite of the frequency of Kimmeridge Clay inclusions, the Jurassic till had a high sand content. This was no doubt acquired from the underlying Sandringham Sands. Evans concluded that the upper chalky till was emplaced during a readvance phase across a stagnating lower till, though both belonged to the same glacial phase. Gallois however stated that many sections elsewhere in west Norfolk showed gradational contacts, and the lower, Jurassic till merely represented a basal layer of slow-moving ice.

Distribution of the tills

It is clear from Gallois' sketch-map (1978, Fig. 1) and from the Old Series Geological Survey maps that the tills are now preserved either on the higher ground of spur crests and hill summits or along the main valleys where the thickest sequences exist. The thinness of the tills on the higher ground and general absence on slopes is a consequence largely of Devensian periglaciation, and 'head' or solifluction loams and gravels of variable lithology and thickness occur widely in west Norfolk. Such 'head' frequently includes till material and has seemingly been misinterpreted as till in a number of earlier publications (West and Donner, 1956; Stevens, 1959; Woodland, 1970).

Of great interest are Gallois' demonstration that tills occupy the floors of the main valleys and his suggestion that the buried valleys represent parts of a pre-glacial river system. Such a situation is not unique, for it recurs west of the Fen basin in Kesteven. Recent work here (Wyatt, 1971; Wyatt et al, 1979; Rice, 1965; Harrod, 1972) has confirmed that systems of west-east valleys excavated in Middle Jurassic rocks are in several instances completely filled with glacial materials. However in Kesteven it is probable that certain north-south valleys, particularly part of the River Witham valley north and south of Grantham and others just south of the scarp crest south-west of Grantham are in

large part glacially rather than fluvially or glacifluvially eroded (Straw, 1969).

It is difficult to accept all the west Norfolk buried valleys as of fluvial origin, even though Gallois argues strongly against a sub-glacial origin. It seems however from his paper that he is considering sub-glacial excavation by meltwaters in the manner of tunnel valleys' (Woodland, 1970) and not direct erosion by glacier ice, although the final two points of those he lists for a fluvial origin in fact testify to such erosion. The west Norfolk tills on all accounts consist largely of locally-derived materials; the Kimmeridge Clay inclusions, Carstone fragments and the high sand content of the Jurassic till, and great quantities of fresh chalk and flint in the upper till, all point to considerable erosion by ice. Indeed the Bawsey tills may well rest in a glacially eroded groove. On a wider scale, the high proportion of Upper Jurassic clay in tills south of the Fens testifies to significant erosion of the central vale of Lincolnshire and the northern Fen basin (Straw, 1958, 1979) and the anomalous size of the Wash gap must owe something to the passage southward of glacier ice. It may well be therefore that, as in Kesteven and at Welton-le-Wold in Lincolnshire (Alabaster and Straw, 1976), pre-glacial valleys orientated generally transverse to ice movement gained thick infills of till, but the gradient of some existing valleys may have been reversed, and other linear depressions some over-deepened may actually have been produced, by the ice itself. Gallois' tentative reconstruction of a former river system does not therefore seem firmly based, for although pre-glacial valleys within the Upper and Lower Cretaceous outcrops obviously survived glacial erosion, those over Upper Jurassic rocks, like those over the Lower Jurassic rocks of the Vale of Belvoir (Straw, 1963; Rice, 1968) probably did not. Depressions on the Fen basin floor revealed by borehole logs would then have been glacially eroded.

Wider field relationships and circumstances of deposition

Although Evans (1975) made no attempt at extra-regional comparison of the tills, Gallois (1978) did relate the Jurassic till of west Norfolk firmly to that of central Lincolnshire (the Wragby Till - Straw, 1969) and with similar tills beneath the Fens, but he did not trace the upper chalky till further afield. However it is not possible to understand fully either the circumstance of deposition of the West Norfolk tills or their significance in broader chronostratigraphic terms unless recourse is made to wider field relationships and this limitation is apparent in both Evans' suggestion of a readvance of ice to account for the upper chalky till and Gallois' view that a single slow-moving ice sheet was responsible for both tills.

The upper chalky till at Bawsey is identical in lithology to chalky tills over the Chalk outcrop of west, central and north Norfolk (Straw, 1965). These latter tills (collectively the Marly Drift), also dissected and affected greatly by later periglacial processes, contain far-travelled erratics and marine materials, for example the large quantities of wave-eroded flint cobbles and pebbles eastward of Docking, which provide ample proof of ice movement from the north down the east coast and not from central Lincolnshire to the north-west.

The lower Jurassic till of west Norfolk is an extension of the Wragby Till of Lincolnshire which was produced by ice streaming south-south-east parallel to the Cretaceous escarpment. However at this stage the Lincolnshire Wolds were also covered by ice, some of which crossed the central Wolds southward into the Bain valley (Straw, 1966) while more crossed the southern Wolds into the Wash area. Near the Bain valley, the Wold ice, laying down a highly chalky till (Calcethorpe Till), abutted the central Lincolnshire ice so that now, in a narrow zone from Hainton (TF 180845) to Kirkby-on-Bain (TF 242623) the Calcethorpe Till directly overlies the highly Kimmeridgian Wragby Till. The Wold ice was deflected

south-south-east by the central Lincolnshire ice, but the line of junction

(not necessarily vertical) between the two may well have fluctuated a

little west and east.

This situation is instructive with respect to the west Norfolk tills.

The Jurassic till was also emplaced by ice moving parallel to the Chalk

scarp (i.e. from the north-north-west) across the pre-glacial valleys

and interfluves of the Lower Cretaceous outcrop, eroding some Upper

Jurassic clay and Lower Cretaceous sandstone. At the same time, ice

moving generally down the east coast crossed the Wash into west and north

Norfolk. This North Sea ice of course effectively stopped the inland

Lincolnshire ice from flowing eastward into north Norfolk, and although

deflected somewhat to flow a little east of south as in the Bain valley,

it may have been sufficiently powerful partly to override the inland ice

and partly to displace the zone of contact a little westward of the Chalk

escarpment. This situation not only accounts satisfactorily for the

stratigraphic and structural relationships of the west Norfolk tills, but

it demonstrates conclusively the essential contemporaneity of the North

Sea and inland ice masses, and of the Marly Drift and the Wragby Till.

There is clearly no requirement for a readvance to account for the upper

chalky till, and two contiguous and partly overlapping ice sheets,

probably moving fairly quickly in view of the basal erosion, would seem

to provide a better explanation for the two highly-contrasted yet intimately-

related tills than a single ice-sheet.

Age of the tills

Gallois notes that the only till younger than the west Norfolk tills

is the Hunstanton Till which reaches no further south than Wolferton

(TF 658286) and which is widely accepted as Devensian. The composition

and disposition of the Hunstanton Till and its association with glacifluvial

features such as eskers and meltwater channels separate it clearly from

the weathered and dissected Marly Drift and the west Norfolk tills (Straw,

1960). In terms of the British Standard Stages the latter should therefore

be referable to either the Anglian or the Wolstonian glacial stages. If
to the former, then the time gap between the west Norfolk tills and the
Hunstanton Till included the Hoxnian and Ipswichian interglacials as
well as the Wolstonian, if to the latter, then only the Ipswichian
interglacial intervened.

Most workers have considered the west Norfolk tills to be Anglian
though, as far as the author can detect, for no firm reason. Baden-Powell
(1948) described the west Norfolk tills as Lowestoft-type, and West and
Donner (1956) accepted his view that they were emplaced during the
Lowestoft Glaciation. Stevens (1959) also accepted without question the
correlation of the Jurassic till beneath the Nar Valley Beds with the
Lowestoft Glaciation, and this seems to have conditioned a correlation
of the Nar Valley Beds with the Hoxnian. More recently Evans (1975)
reversed the argument and tentatively regarded the west Norfolk tills as
Anglian because in places they appeared to be overlain by the Nar Valley
Beds! Shotton et al (1977) concurred with this opinion, and admitted
evidence for one major lithological unit of chalky till over East Anglia
(Perrin et al, 1973) even though they appreciated the difficulties of
correlation that arose between deposits east and west of the Fens. So
constrained, rather than for any argued reason, they placed the Wragby
Till of Lincolnshire also in the Anglian. Gallois (1978) remained non-
committal on age, but confirmed the continuity of the Wragby Till beneath
the Fens with the west Norfolk Jurassic till and also the contemporaneity
of both the west Norfolk tills.

The argument for a single complex of chalky tills over East Anglia
is not however overwhelming. In the first instance, an apparent absence
of examples of superimposition of chalky tills of different ages should
not be surprising. During each glaciation of eastern England, ice-sheets
have destroyed most of the drifts and soils in their tracks (Wymer and
Straw, 1977) and just as the Devensian tills of northern England rest

directly on bedrock so do both Wolstonian and Anglian chalky tills, the latter surviving only outside the range of Wolstonian ice. Secondly it is being increasingly recognized that if successive ice-sheets traverse identical outcrops then closely similar tills, yielding closely similar heavy mineral assemblages for example, may result (Wymer and Straw, 1977; Shotton et al, 1977; Gallois, 1978). The essential point is that the Jurassic till of west Norfolk does not have to be correlated with Lowestoft Till merely because of its lithological similarity. In fact lithological similarity should not be pressed too far, because while the west Norfolk till contains much Lower Cretaceous material and virtually no Triassic indicating ice flow from the north-north-west, the Lowestoft Till contains little Lower Cretaceous but noticeable quantities of Triassic, including recognizable lumps of Keuper Marl, and some Carboniferous, confirming ice flow from the west-north-west.

Against this majority view, Straw (1960, 1965, 1969, 1973, 1979) has argued consistently that the chalky tills of Lincolnshire and of central and north Norfolk are of Wolstonian age. There is no evidence for more than one period of valley incision between the chalky tills and the Devensian tills, the Calcethorpe and Wragby tills of Lincolnshire are overlain extensively only by Devensian gravels and Flandrian alluvium, the Marly Drift is intimately related to the overlying outwash gravels accepted by, for example, Sparks and West (1972) and Shotton et al (1977) as Wolstonian, and a Wolstonian limit across Norfolk from Weybourne and Aylsham by way of Norwich and Diss to the southern Brecklands can be identified (Straw, 1974, 1979).

Recently, biological evidence has supported a Wolstonian age for the Lincolnshire chalky tills. At Tattershall (TF 207567) Ipswichian interglacial depsoits rest indubitably on Wragby Till (Girling, 1974; Shotton et al, 1977). At Welton-le-Wold (TF 282884) a meagre but probably

Hoxnian mammalian fauna and three Acheulean hand-axes have been recovered from gravels beneath chalky tills (Welton and Calcethorpe Tills) which are demonstrably older than Devensian, and are laterally contiguous with the Wragby Till (Straw, 1966; Alabaster and Straw, 1976). In Norfolk, at Beetley (TF 973187) Ipswichian deposits rest on outwash gravels of the Marly Drift. In fact, nowhere over Lincolnshire, the east Midlands or central and west Norfolk are the chalky tills overlain by fossiliferous sediments of proven Hoxnian or older date. Also it can be noted that wherever valleys have been incised into and through the chalky tills, fluvial terrace sands and gravels within these valleys have without exception been considered of Ipswichian or younger age.

Age of the non-glacial deposits

The arguments presented above point strongly to a Wolstonian rather than an Anglian age for the west Norfolk tills, and it is pertinent therefore to examine briefly the implications of such a designation on three groups of non-glacial deposits in west Norfolk described by Gallois (1978).

Above and probably conformable with the chalky tills are the Nar Valley Beds, succeeded unconformably by the Tottenhill Gravels. In north Norfolk, the Hunstanton raised beach, probably contemporaneous with the upper part of the Tottenhill Gravel lies beneath the Hunstanton Till.

The Hunstanton raised beach has long been ascribed to the Ipswichian interglacial and correlated with the buried beach at Sewerby in east Yorkshire, but there is one feature common to both that is worth comment. The Hunstanton Till and the Holderness tills are believed by many to be Late Devensian (Shotton, 1977; Madgett and Catt, 1978) emplaced after about 18,250 years B.P., but the only deposits between both shingle beaches and the overlying tills are relatively thin periglacial (aeolian and/or soliflual) materials with no observable weathering horizons above or below; meagre accumulations indeed if the beaches are Ipswichian and some 50,000 years elapsed between shingle accretion and till deposition!

However, the Hunstanton Till might be of late Early Devensian date (Straw, 1961, 1979) and if the beaches were formed no earlier than the close of the Ipswichian (or even into the Early Devensian) then this inconsistency is reduced.

Gallois showed the Jurassic till to pass upward through varved clays into the Nar Valley Beds. The latter comprise lower freshwater and upper marine units, and contain a flora and fauna indicative of the climatic sequence of at least the first half of an interglacial period, by which time sea-level had reached about 30 m O.D. The Nar Valley Beds have been generally regarded as Hoxnian since the work of Stevens (1959) though previously Baden-Powell (1934, 1953) for example had claimed the them as Last (Ipswichian) interglacial. Stevens' palynological evidence in itself was not conclusive, substantial differences with the Hoxne pollen diagram were noted, and her dating of the deposit at least as presented in the paper would seem to have relied more heavily on its position above a Lowestoft-type (ipso facto Anglian) till, supported by its height up to at least 24 m O.D. which might be considered to place it outside the Ipswichian range (West, 1972). However, it must be noted that the Nar Valley Beds lie <u>within</u> a valley system, a location generally held characteristic of Ipswichian deposits (Sparks and West, 1972), that the erosion between the lower freshwater unit which terminates toward the end of pollen zone IId and the upper marine unit which commences in zone III (Stevens, 1959) may be compared with the base-level oscillation frequently observed in Ipswichian aggradation deposits (Sparks and West, 1972), and that ostracods in the Nar Valley Beds differ from marine Hoxnian ostracod assemblages in Britain and western Europe (Lord and Robinson, 1978).

Gallois (1978) separated the Tottenhill Gravels into two units, correlated the upper one with the Hunstanton raised beach and demonstrated its unconformable position on the lower unit, on the Nar Valley Beds and on Kimmeridge Clay. This Upper Tottenhill Gravel is a strandline deposit

lying between 3 and 7 m O.D., but the lower gravel unit, also unconformable on the Nar Valley Beds has some characteristics of a channel-fill.

Chronology

It should be apparent that the chronology of the tills and associated deposits of west Norfolk has not been established to date with any degree of certainty.

Gallois merely referred the Nar Valley Beds to a temperate climatic phase following the cold climate witnessed by the chalky and Jurassic tills. He related the Lower Tottenhill Gravel to an early phase of the Hunstanton glaciation, and the Hunstanton raised beach and Upper Tottenhill Gravel to a succeeding warmer period, followed by the Hunstanton glaciation.

The traditional interpretation would place the chalky and Jurassic tills in the Anglian and the Nar Valley Beds in the Hoxnian. If the Hunstanton Till is Devensian and the Hunstanton raised beach Ipswichian then the Lower Tottenhill Gravel would conveniently represent the Wolstonian.

However, a case has been argued above for regarding the chalky tills of west Norfolk as Wolstonian, the corollary of course is that the Nar Valley Beds were aggraded in the first half of the Ipswichian. If the Hunstanton glaciation took place in the late Early Devensian, then the Lower Tottenhill Gravel and the Hunstanton raised beach/Upper Tottenhill Gravel can be referred to the late Ipswichian and Early Devensian respectively.

The Hunstanton raised beach and Upper Tottenhill Gravel would testify to a sea-level a little higher than present in the early Early Devensian, whereas the older Lower Tottenhill Gravel suggests some channelling of the Nar Valley Beds when sea-level was rather below present. Apart from the probability that the Lower Tottenhill Gravel represents a short-lived even catastrophic event, too little detail is known of the manner of recession of sea-level from an Ipswichian 'high' to deny the possibility of oscillatory movements over a period of perhaps some tens of thousands of years.

The point of this latter discussion is not so much to prove a particular chronological succession as to demonstrate that the timing of events recorded in the deposits and features described by Gallois and others in west Norfolk is capable of a different and in the author's view equally valid interpretation from that which has prevailed to date. The broader purpose of the paper has been to show that the age of the chalky tills of west Norfolk is very probably Wolstonian and not Anglian, that as a consequence the Nar Valley Beds deserve serious and independent re-assessment, and that relative land/sea movements during the late Ipswichian in eastern England were more complex than has so far been demonstrated.

A FROST CRACK SYSTEM AT COVEHITHE CLIFF, SUFFOLK

R.G. WEST[*]

The cliff at Covehithe (G.R. TM 529820) has in the last few years been subject to rapid erosion. In March 1978 the cliff sections so exposed revealed a system of frost cracks penetrating the sands and gravels of the Westleton Beds (Hey 1967). Eight such cracks were seen. Their disposition in relation to the road ending at Covehithe Cliff is shown in Figure 1, which also sketches the stratigraphy at each frost crack site. The cliff section is composed of a number of sedimentary units (see section in Figure 48, West 1980). At the base are the laminated clays of the Baventian stage, which often form a ledge to seaward of the cliff. These have been described recently by West, Funnell and Norton (1979). A thin bed of red loamy sand, up to 60 cm thick and shelly in places, overlies the Baventian clays unconformably. This sand is overlain by up to 3.5 m of intertidal laminated beds of clay, silt and sand, showing bioturbation. The Westleton Beds sands and gravels, up to 5 m thick, lie unconformably on these intertidal sediments. Above them, thickening south of the road, is a series of sands with minor associated gravels, up to 5 m thick, with a pebble content described by Hey (1967). This unit is sealed by a reddish loamy sand up to 1.5 m thick and the modern soil.

The upper limits of the cracks, where they widen rapidly to 10-20 cm, lie near the junction of the Westleton Beds and the upper sands and gravels. Most of the cracks are sealed by a thin lag gravel at the base of the upper sands and gravels. The cracks narrow rapidly to a few centimetres wide and carry on down as narrow cracks penetrating the Westleton Beds and in some examples the underlying laminated beds, as indicated in Figure 1.

[*]Botany School, Downing Street, Cambridge, CB2 3EA.

West

Fig. I. Disposition of frost cracks in Covehithe Cliffs

The cracks are unusual in combining narrowness with a good depth of penetration. The depth of penetration suggests they are not desiccation cracks, but rather thermal contraction cracks associated with freezing of the ground (Washburn 1973). No development of massive ice-wedges or sand-wedges seems to have occurred. The reason may be that the freezing period was short-lived, or that the coarse-grained sediments were incompressible and therefore thermally relatively incontractible or that they were free-draining with a low water content.

The disposition of the cracks indicates the presence of a former land surface on an eroded surface of the marine Westleton Beds. This land surface was subjected to deep freezing. Subsequently the upper sands and gravels aggraded under a fluviatile regime.

The dating of the freezing episode is uncertain in view of the unknown age of the upper sands and gravels. It must be post-Westleton Beds, i.e. post-Bramertonian (Funnell, Norton & West 1979). If the upper sands and gravels are Anglian, their lithology indicates that they pre-date the chalky boulder clay (Lowestoft Till) ice advance. so that the freezing period may be in the earlier part of the Anglian cold stage. It may then correspond to an ice-wedge network seen penetrating Cromerian sediments at Corton (Gardner & West 1975). If the upper sands and gravels are pre-Anglian, then the freezing period must be in a cold stage between the Bramertonian and the Cromerian. Two such cold stages are documented on the Norfolk coast, the Pre-Pastonian and the Beestonian. Ice-wedge casts and a polygon system are known from the Beestonian (West 1968, 1980), but not certainly from the Pre-Pastonian. Further work on the coastal sections of the Covehithe Cliff would probably make a more accurate date possible.

HISTORY AND PROGNOSIS OF SUBSIDENCE AND SEA-LEVEL CHANGE IN THE LOWER
YARE VALLEY, NORFOLK.

B.M. Funnell*

Abstract

A model of subsidence and sea-level change in the lower Yare valley
is proposed, based on the levels of successive freshwater and estuarine
deposits over the last 8000 years. A projection of relative land-sea
changes for the next 2000 years is made on the basis of continuing
subsidence at the rate of 1.5m per 1000 years, and continuing sea-level
fluctuations of an amplitude of about 1.5m and wavelength of about 1000
years.

Introduction

Many difficulties and uncertainties confront any attempt to elucidate
the history of land-sea level changes on the East Anglian coast, but some
of the fullest information on which such an attempt can be based is
contained in the alluvial stratigraphy of the east coast valleys of the
rivers Bure, Yare and Waveney. These were originally studied by Jennings
and Lambert in their investigations of the origin of the Broads (Jennings
1952, Lambert and Jennings 1960, see also Ellis 1965), and latterly also
by Coles in his investigations of the foraminifers and palaeogeography
of the central Broadland during the Holocene period (Coles 1977).
Meantime Tooley (1978), working on deposits on the more stable coast of
Lancashire, has deduced a useful detailed history of sea-level changes over
the last 9000 years. Putting these results together it is now possible
to devise a history of subsidence and sea-level change in the lower Yare
(Figure 1) that seems to account adequately for the known spatial and
temporal extent of freshwater and estuarine deposits in the lower Yare valley

*School of Environmental Sciences, University of East Anglia, Norwich NR4 7

Previous models

Few previous attempts have been made to interpret the history of land-sea level changes in the vicinity of Great Yarmouth. The earlier interpretations, based mainly on archaeological, but in part also on biological evidence, were intended to help understanding of the history of excavation and subsequent flooding of the Broads (Green and Hutchinson 1960). More recent attempts were made in connection with the engineering evaluation of the Yare valley (flood protection) barrier (Rendel, Palmer & Tritton 1977). Neither of these attempts have proved totally satisfactory. The mainly archaeological and biological evidence from the Yarmouth spit was thought to indicate some large and seemingly inexplicable land-sea level changes in post-Roman times, and the tide-level evidence from the last 70 years, used by the engineers, implied a minimal (+0.3 $\pm$ 0.2m per 1000 years) trend that is small by comparison with the changes seen over the last few thousand years.

The basic stratigraphical succession in the Lower Yare valley is:

5. Upper Peat, a reed and brushwood peat deposited after the withdrawal of estuarine conditions!

4. Upper Clay, an estuarine clay deposited 2000 - 1500 BP, its top at about -0.5m O.D.

3. Middle Peat, a brushwood and reed peat deposited 4500-2000 BP across the entire valley.

2. Lower Clay, an estuarine clay deposited 7500-4500 BP, its top at about -5.5 to -6.5m O.D.

1. Lower Peat, a mainly reed peat deposited before 7500 BP.

These beds record the alternation of marine and freshwater conditions in the lower valley and the fluctuation of sea-level in relation to deposition in the valley.

The present model

No attempt is made here to justify fully the model that is presented in this paper, but the chief points used in its construction need to be explained.

First, it is assumed that the curve of sea-level changes elucidated by Tooley (1978) is essentially correct, at least for N.W. Europe. It corresponds rather closely, both in frequency and amplitude, with a similar curve deduced by Mörner for southern Sweden (Mörner 1976).

Secondly it is assumed that we know accurately the present level of the top and feather edge of the Upper Clay which accumulated in Broadland in Roman times (dated by ^{14}C to around 1600 BP (= 400 AD) and occurring now at between -0.50 and -0.70m O.D.). Having deduced from the contained microfaunal evidence that the intertidal clay sedimentation occurred to about MHWS (in present-day terms + 0.50m O.D.) we can infer a simple relative fall of the land in relation to the sea since 1600 BP of at least 1.0m. However, at 1600 BP Tooley records a relatively high sea-level of + 1.75m compared to the present-day. Therefore the total absolute fall of the land, measured by the present level of the top of the 1600 BP estuarine clay relative to the 1600 BP sea-level is from + 2.25 to -0.50m, ie. 2.75, or a subsidence rate of about 1.7m per 1000 years. A similar calculation can be made in relation to the top of the much older and deeper Lower Clay which occurs at depths of between -6.0 and -20.0m O.D. beneath the lower Yare alluvium. Here we can again be quite certain, from microfaunal evidence, that deposition of the estuarine clay ceased in a high salt marsh environment (= MHWS or about + 0.95m*) at about, (and this figure by comparison is very approximate), 4500 BP. If we use a figure for the present-day level of

---

(*The O.D. level for MHWS given here differs from that used for the Upper Clay because the top of the Upper Clay is observed at the inland end of the lower Yare valley and the top of the Lower Clay is observed at the seaward end.)
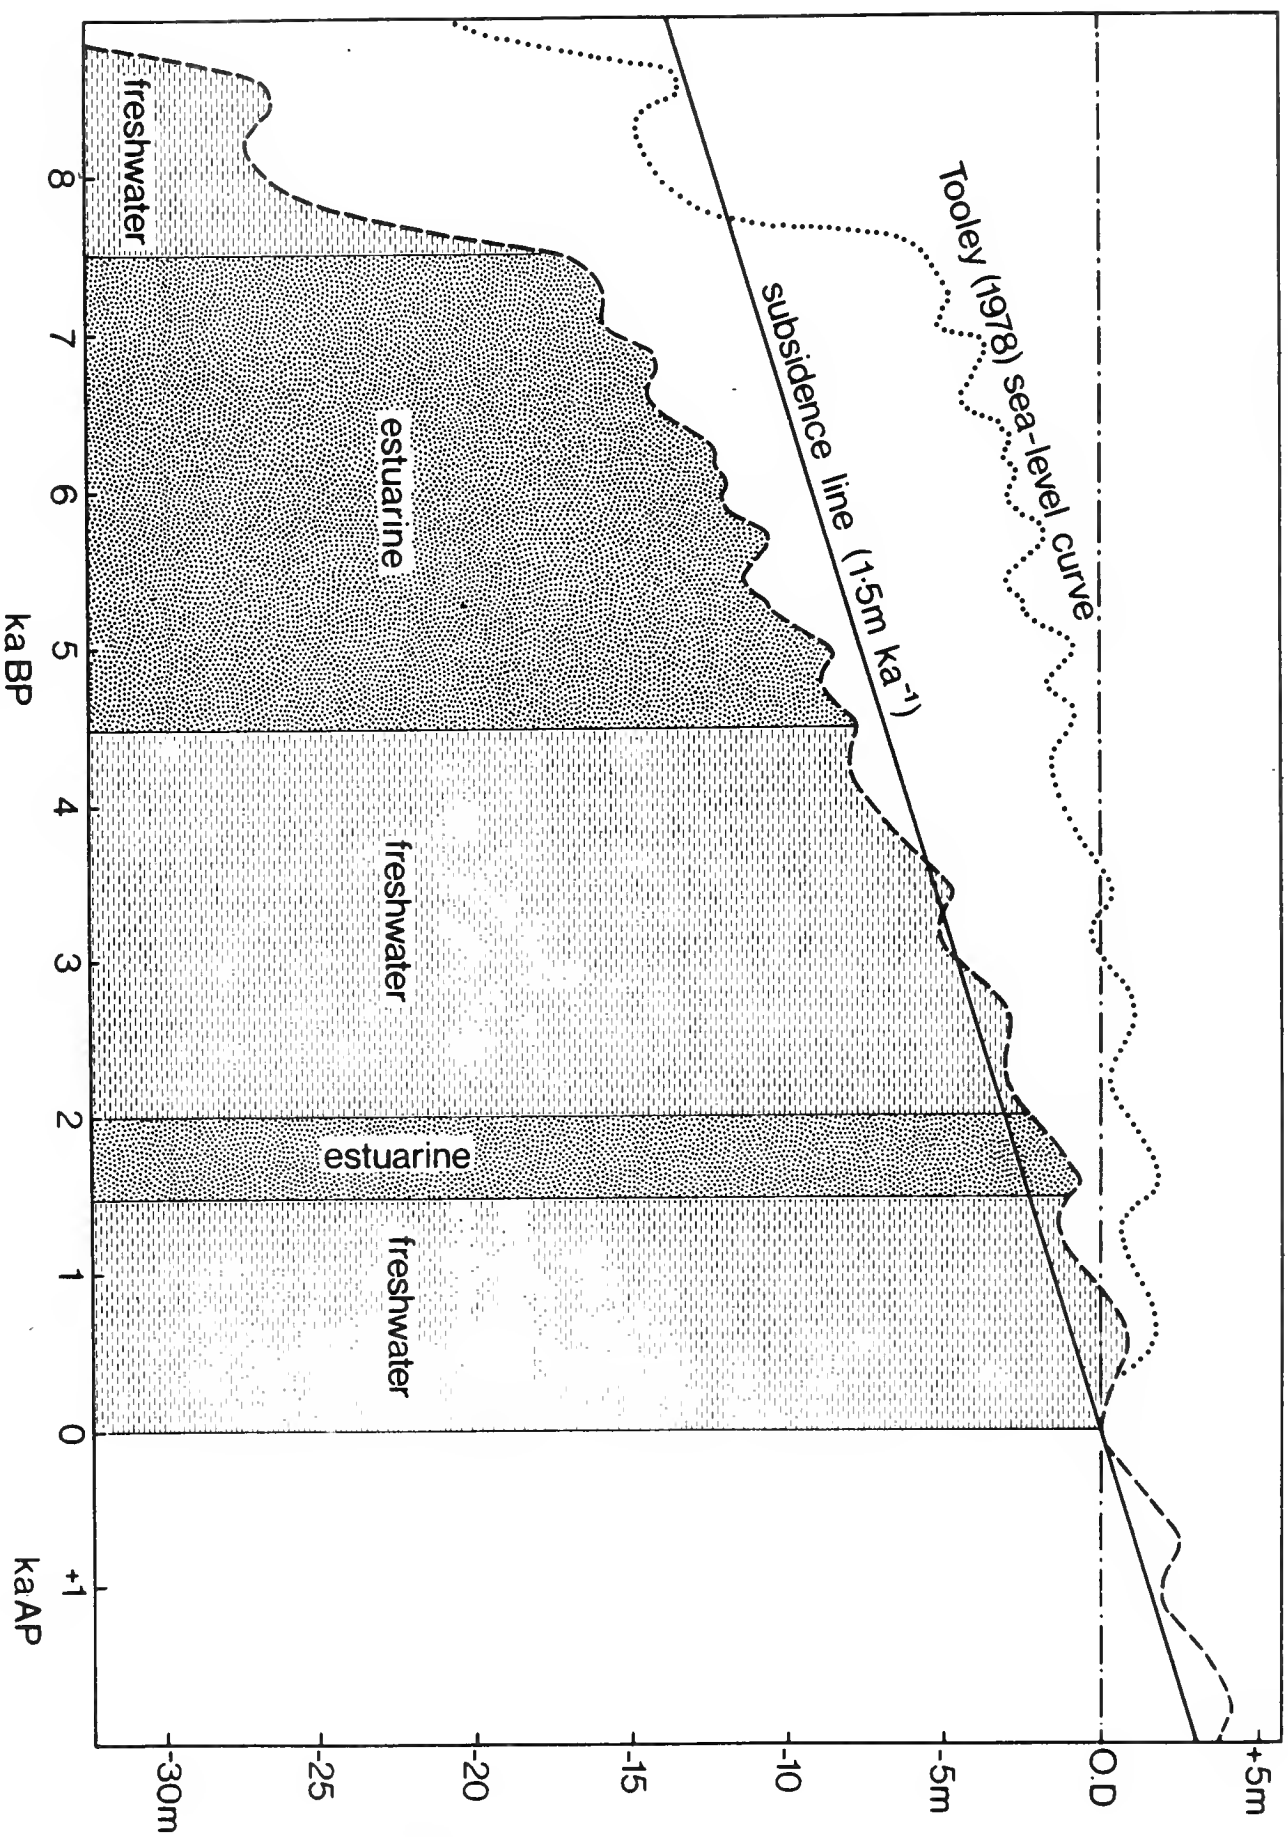

Figure 1. Land-sea level changes in the lower Yare valley 8000 BP (= 6000 BC) to 2000 AP (= 4000 AD). The sea-level curve of Tooley (1978), obtained from a coastal area of no net subsidence or elevation, has been modified to incorporate a continuing rate of subsidence of 1.5 ka^{-1}. The resultant land-sea level curve has been applied to the lower Yare valley and correlated to alternations of freshwater and estuarine conditions in the valley from 8000 BP to the present-day. It is speculatively continued to the year 2000 AP.

the top of this Lower Clay of -6.0m, and add +0.95m to give the total

simple fall in level since deposition, we get 6.95m in approximately

4500 years. However Tooley's sea-level curve stands at a minimum of

-1.0m below present O.D. at around 4500 BP and levels as low as

-1.75m occur not long before and after this date. Therefore the

actual subsidence since 4500 BP is less, either 5.95m (6.95 - 1.0m;

corresponding to 1.3m per 1000 years) or 5.20m (6.95 - 1.75m;

corresponding to 1.2m per 1000 years). There are many uncertainties

in making such calculations. The two most important are the

uncertainty in the age of the level determined and the vertical

variations of that level from place to place. There is also, of

course, the uncertainty of the Tooley curve of sea-level change itself.

However, if we re-calculate with slightly different but still realistic

ages, or slightly different but still realistic levels, or make

slightly different tidal level assumptions about the environment of

deposition of the critical sediment, most of the answers continue to

give a subsidence rate between 1.2 and 1.8m per 1000 years. Figure 1

is therefore basically Tooley's (1978) sea-level curve, actually dotted

in on the figure, re-drawn with a subsidence rate of 1.5m per 1000 year

added or incorporated. It is also extended 2000 years into the future

by continuing the 1.5m per 1000 year subsidence rate and repeating the

last two cycles of the Tooley sea-level curve. Alternative ways of

extending the Tooley cycles could have been chosen but they would not

substantially affect either the amplitude or frequency of the result.

Similarly other subsidence-rate lines, especially between 1.2 and

1.8m per 1000 years, could have been chosen, but these too would not have greatly affected the resultant levels. (The choice of a straight subsidence-rate line is of course a simplication, but it is not known to be contradicted by any currently available data).

The most interesting aspect of the land-sea level curve drawn on such a simple basis is that it is consistent with a great deal of what we know about the alluvial history of the Yare valley. Fresh-water gives way to estuarine conditions (Lower Clay overlies the Lower Peat) at about 7500 BP and at a present depth of about -20m as the most rapid episode of Holocene post-glacial sea-level rise occurs. At about 4500 BP (-6.0m O.D.) estuarine deposition is replaced by fresh-water (Middle Peat overlies Lower Clay) as the rate of sea-level rise slackens off and rapid estuarine deposition overtakes the continuing rate of subsidence. Estuarine conditions return after the deposition of the brushwood peats (Upper Clay rests on Middle Peat), from 2000 BP onwards at depths of about -2.0m, and culminated at 1600 BP at a depth of -0.7m. Freshwater conditions returned (Upper Peat developed in places on top of the Upper Clay) from about 1500 BP (= 500 AD) as the estuarine conditions withdrew at a time of sea-level fall. The sedimentary record fails to record events adequately from this time onwards because of increasing human intervention with drainage, etc. However, we can see the sea-level fall bottoming at about 1300 BP (= 700 AD) would have assisted the mediaeval abstraction of peat whereas the sea-level rise culminating at about 700 BP (= 1300 AD) corresponds with the period of decline of the Broadland peat diggings and their conversion into Broads by flooding.

Lastly, the decline of sea-level since the 14th century and the apparent coincidence of the present-day with a turning point of the Tooley cycle can be seen as a possible reason for the last of short-term evidence for subsidence at the East Anglian coast at the present-day.

Comparison with previous interpretations

Interpretations of land-sea level change in the vicinity of Great Yarmouth were, as mentioned previously, made by Hutchinson and Green on the basis of a variety of archaeological and biological observations for the period from around 1600 to 600 BP (= 400 to 1400 AD). None of these interpretations are exceptional, ie. they can be accommodated within the limits of error by the changes as graphed on Figure 1. All, that is, except the inference of a relative sea-level of -4.0m at around 700 BP, precisely coinciding with the time of the great flood of 1287 AD! That conclusion was reached on the assumption that the barnacle Balanus balanoides, and the mollusc Mytilus edulis were essentially intertidal organisms, and that their occurrence at depths of c. -5.0m O.D. implied subsequent land subsidence or sea-level rise of 4.0m or so in the intervening 700 years. However, both species do occur sub-tidally in appropriate circumstances and the conclusion drawn regarding relative contemporary land-sea levels is not necessarily valid. No other evidence requires sea-level at Great Yarmouth to have been sensibly different to the present c. + 0.2m O.D. at 700 BP, although the tidal range of the river side of the spit at its proximal end may have been less because of its longer southward extension towards its then opening to the sea near Lowestoft.

Interpretations of recent land-sea level changes in the vicinity

of Great Yarmouth made by civil engineering consultants (Rendel,

Palmer & Tritton 1977) have relied on the interpretation of tidal-

gauge and maximum tidal level records. These show cyclic fluctuations

over the 70 or so years for which they are available with no very

clearly defined systematic trend either upward or downward. The only

comment that can be made here is that this is precisely what would be

expected at the present point of conjunction of the subsidence and

sea-level curves as expressed on Figure 1.

Fallability of the prognosis

Although Figure 1 has been boldly projected from 8000 BP through

the present day to 2000 AP (= c.4000 AD) it must be clearly understood

that this is not necessarily what is going to happen. It just looks

like the most likely outcome if trends identified in the past record

continue into the future. The Tooley sea-level curve could be about to

change its character at the present time, just as it has, as you can

see, in the past. Also the subsidence line could be about to change

either its rate (= quantity) or its direction (=sign). Subsidence has

apparently been the rule in the Post-Glacial epoch on the east coast

of East Anglia, but it has by no means always been the rule in the last

few 100 ka of the Quaternary period. It could reverse itself again.

It would of course be possible to refine the subsidence line and for

that matter the Tooley curve, by additional augering, interpretation

and dating of the Yare valley alluvial stratigraphy. This could

considerably improve the accuracy of the graph of the last 8000 years

of land-sea level changes in the lower Yare. It would not, for the reasons just quoted, necessarily increase the reliability of the projection into the future. Nevertheless even the present projection into the future should be of interest to those concerned with planning human reaction to land-sea level changes. If nothing more it is one possible future, and credible evidence that it is not likely to happen should be adduced before ignoring the possibility.

Figure 1. Land-sea level changes in the lower Yare valley 8000 BP
(= 6000 BC) to 2000 AP (= 4000 AD). The sea-level curve of Tooley
(1978), obtained from a coastal area of no net subsidence or elevation,
has been modified to incorporate a continuing rate of subsidence of
1.5 ka^{-1}. The resultant land-sea level curve has been applied to the
lower Yare valley and correlated to alternations of freshwater and
estuarine conditions in the valley from 8000 BP to the present-day.
It is speculatively continued to the year 2000 AP.

THE KIMMERIDGE CLAY IN NORFOLK

R.W. GALLOIS*

Introduction

The Kimmeridge Clay was first recognised as a separate formation by William Smith on his 'Improved Table of Strata' (1815-6) where he called it the Oaktree Clay. Webster (in Englefield 1816) subsequently used the term Kimmeridge Clay for the same beds, taking the name from the village on the Dorset coast where there are fine cliff sections. The formation has an extensive outcrop and subcrop in England. The outcrop runs in an almost continuous strip from Dorset to North Yorkshire and is broken only in north Dorset, Wiltshire, between Buckinghamshire and Cambridgeshire and across the Market Weighton axis in Humberside/ North Yorkshire, where the formation has been removed by erosion during the late Jurassic and Lower Cretaceous. The subcrop underlies the whole of the land area to the east of the outcrop with the exception of a large area beneath East Anglia (on the London Platform) and a smaller area on the Market Weighton Axis.
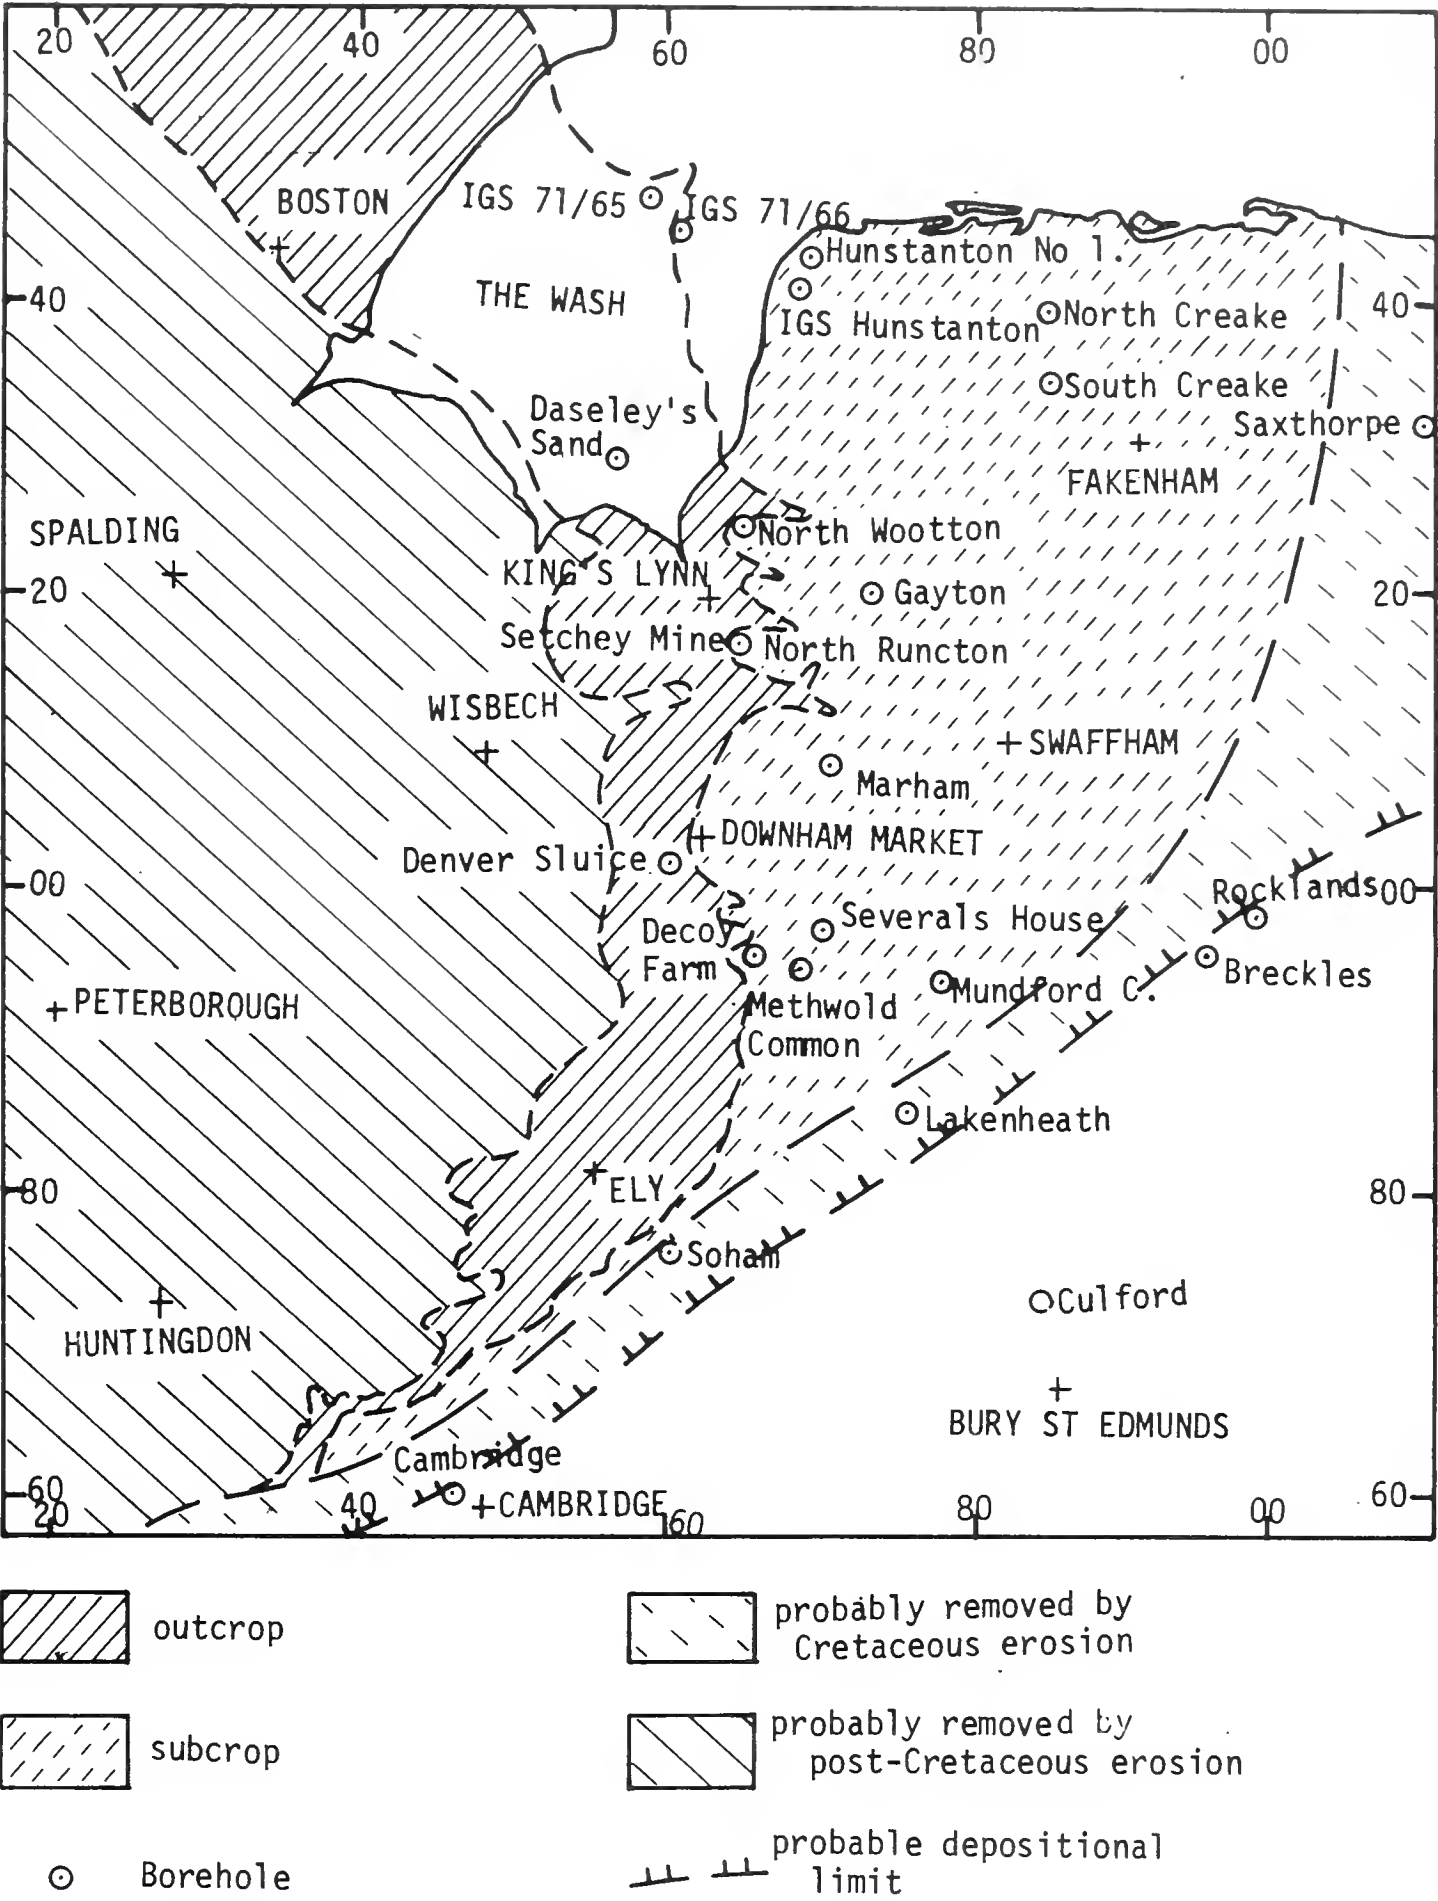

Throughout much of its outcrop the Kimmeridge Clay is largely obscured by drift deposits or weathered material and for this reason most of the important contributions to its stratigraphy have been made from studies of the Dorset cliff sections. The formation has had little economic value in the past. It has been used on a limited scale for brickmaking at many localities and much of the stratigraphical

* Institute of Geological Sciences, London SW7

Published by permission of the Director, IGS.

information obtained from inland areas has come from small pits dug

for this purpose. Most of these are now completely degraded and,

because of their geographical isolation from one another and from the

Dorset coastal sections, the faunal and lithological material collected

from them is stratigraphically useful only where the complete local

sequence is known from continuously cored boreholes.

The most celebrated attempts to exploit the Kimmeridge Clay have

been those which sought to extract commercial quantities of oil from

the numerous thin seams of oil shale (kerogen-rich mudstones that

yield appreciable quantities of oil when retorted at 400 to $500^{\circ}C$)

which occur in the middle and upper parts of the formation. The

occurrence of oil shales in the cliffs at Kimmeridge Bay has been known

since Iron Age times. The most famous Dorset seam, the Blackstone,

was used locally as a coal substitute, both domestically and industrially,

and yielded at various times in the 16th to 19th centuries products

ranging from lubricating oil to fertilizer and a sanitary deodorizer.

Similar combustible shales have been recorded elsewhere in Dorset and in

Wiltshire, Norfolk, Lincolnshire and Scotland.

The Kimmeridge Clay is poorly exposed in Norfolk and little

detailed work has been done on its stratigraphy until relatively

recently. The highest part of the formation crops out along the

eastern edge of Fenland between King's Lynn and Southery but the

bulk of the formation is overlain by the Pleistocene and Recent

deposits of Fenland and The Wash (Fig. 1). Although temporary sections

have become available from time to time in the outcrop they have usually

Fig. 1 Distribution of the Kimmeridge Clay in Norfolk

been deeply weathered and have produced little stratigraphical information. The lower part of the formation is everywhere covered by drift deposits within the county and is known only from boreholes.

The first published record of the Kimmeridge Clay in Norfolk was that of William Smith on his geological map of the county (1819). On this he noted that the "Oaktree Clay [Kimmeridge Clay] was part slaty and bituminous as at Kimmeridge in Dorset". Rose (1835, p. 175) subsequently recorded inflammable shales "that burned like cannel coal" in the Kimmeridge Clay in a brick pit at Southery [probably TL 617 958] and oil seepages, supposedly derived from the Kimmeridge Clay, were noted in the Puny Drain at Setchey, Norfolk [TF 626 145] (Forbes Leslie, 1917).

It was largely on the evidence of these   seepages, and the possible prospect of finding oil shales comparable to those that had been worked at Kimmeridge, that oil-shale exploration was begun in Norfolk during the First World War. A pilot operation was set up at Setchey and more than 60 cored boreholes were drilled in the area between the Gaywood River at King's Lynn and the River Wissey at Hilgay, between 1916 and about 1923. The full-scale retorts at the Setchey works were never completed and a small mine and opencast pit dug for the pilot plant were closed. There was little activity after 1923.

Because of the secrecy surrounding these operations few details have survived from the majority of the boreholes. However, Pringle (1923) was able to examine and sample three continuously cored boreholes drilled in Methwold Fen in south-west Norfolk and until recently these provided the most detailed sections of the Kimmeridge Clay in the county.

Two of the boreholes, at Methwold Common [TL 679 941] and Severals

House [TL 692 964], penetrated the full thickness of the formation.

Pringle concluded from his palaeontological studies that the full

sequence of Kimmeridgian zones appeared to be present in both boreholes.

He suggested that the Norfolk Kimmeridge Clay was attenuated due to slow

deposition since the boreholes proved about 38 m of beds that were

the time-equivalent of about 500 m of beds in Dorset.

In 1970-71 the IGS drilled continuously cored boreholes at Hunstanton,

Gayton and Marham and at two sites in the central part of The Wash and

these provided sequences through the upper part of the Kimmeridge Clay.

In the following year 20 cored boreholes were drilled through all or

part of the Kimmeridge Clay in the area between the southern part of

The Wash and Denver Sluice as part of the engineering feasibility study

for the Wash Water Storage Scheme (Gallois 1979).

The search for hydrocarbons in East Anglia in recent years has

provided a relatively accurate picture of the extent of the subcrop of

the Kimmeridge Clay in Norfolk. The full thickness of the formation was

penetrated by the North Creake Borehole (Kent, 1947) and subseqently

by boreholes at Hunstanton and South Creake. Cretaceous rocks were

proved to rest on pre-Kimmeridgian rocks in deep hydrocarbon boreholes

at Saxthorpe, Rocklands, Breckles, Lakenheath, East Ruston and Somerton,

in the deep IGS boreholes at Cambridge, Soham and Trunch and in old

water supply boreholes at Culford and Lowestoft. Some of the more

important boreholes to have penetrated the outcrop and subcrop are

shown in Fig. 1.

Stratigraphy

The large amount of continuous core made available by the Wash

Water Storage Feasibility Study enabled the stratigraphy of the Kimme-

ridge Clay of Norfolk, and in particular lateral variations in the sequence,

to be studied in detail for the first time. The lithological and

faunal sequences were found to be remarkably constant throughout the

500+ sq. km. of the study area and this enabled a standard sequence

to be described consisting of 48 distinctive beds which were defined

on the basis of a combination of lithological and faunal characters

(Fig. 2 after Gallois and Cox 1976 and Cox and Gallois in Gallois 1979).
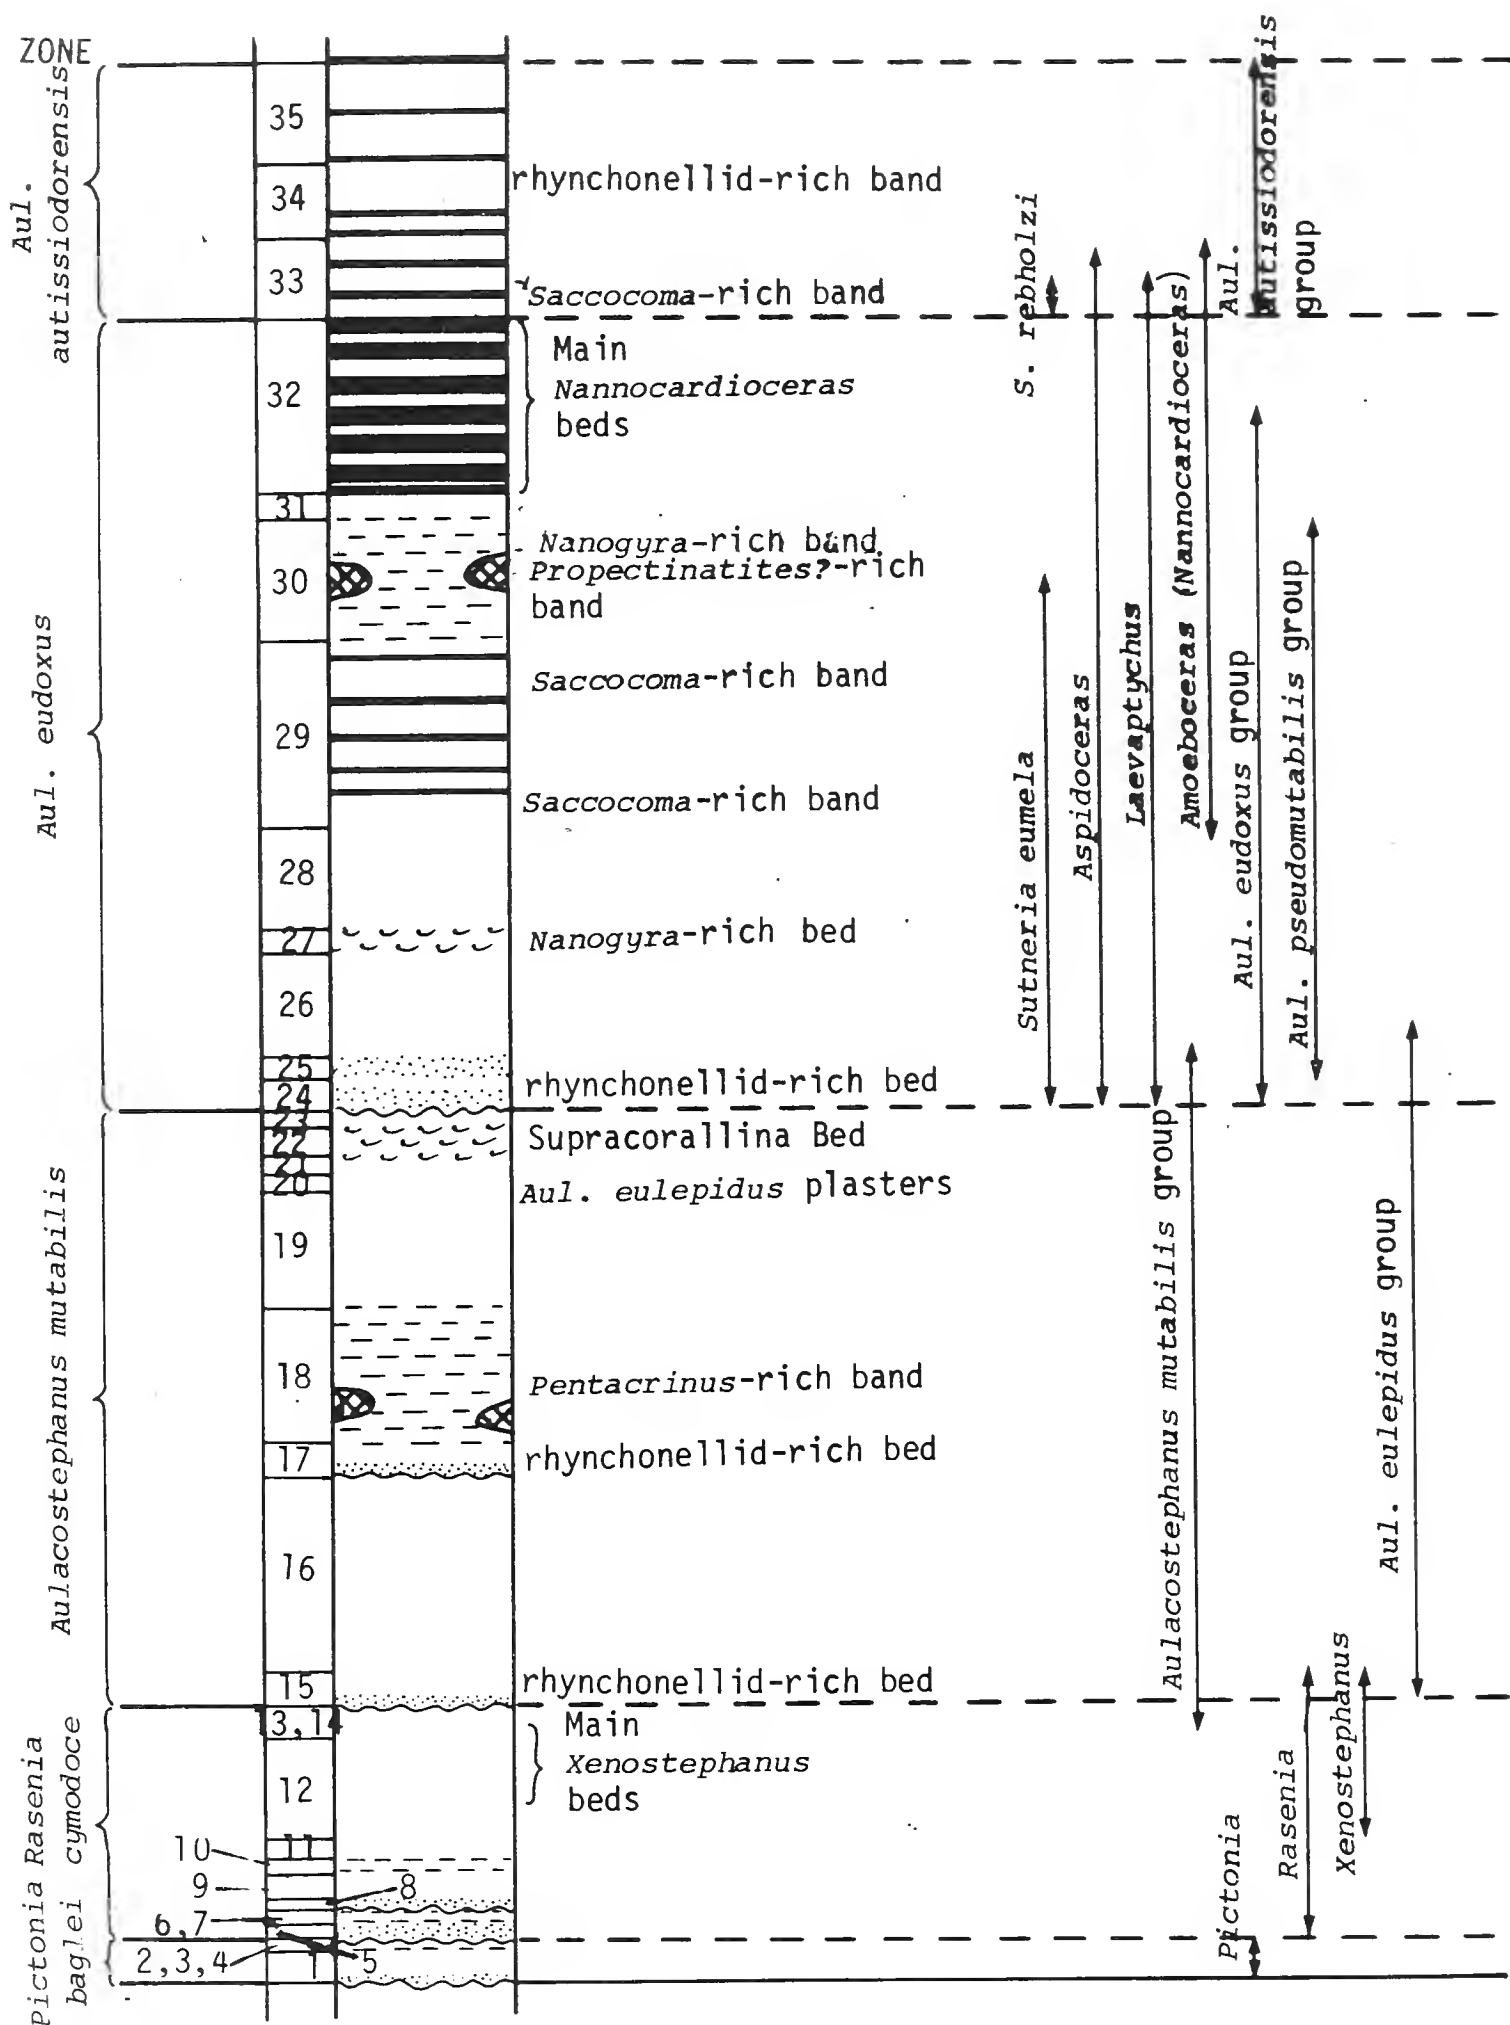

At its most complete the Kimmeridge Clay in Norfolk is about 130 m

in thickness. It thins southwards from this maximum beneath the central

part of The Wash to about 100 m at King's Lynn, 60 m at Downham Market

and nothing in the Mundford area (Fig. 1). This thinning is made up

of two components acting in the same direction. The first component

is a contemporaneous attenuation in sedimentation as the London Platform

is approached and the second is the overstep of the Sandringham Sands.

Comparison of selected groups of beds in boreholes between The Wash

and Denver Sluice has shown that the attenuation occurs without any

noticeable change in lithology and without intraformational erosion.

The Kimmeridge Clay of Norfolk is made up of a complex sequence

of small-scale rhythms. In the lower part of the Lower Kimmeridge Clay

these rhythms consist of thin silts or silty mudstones overlain by

dark grey mudstones which in turn are overlain by pale grey calcareous

mudstones. In the upper part of the Lower Kimmeridge Clay and in the

Upper Kimmeridge Clay the rhythms consist of brownish grey kerogen-rich

mudstones (oil shales) overlain by dark grey mudstones and then by pale grey calcareous mudstones, the last named sometimes including thin beds or doggers of muddy limestone (cementstone). Many of the individual rhythms and limestones can be correlated throughout Norfolk. Superimposed on this rhythmic sequence are broader lithological changes, from more to less calcareous and from more to less kerogen-rich, which can be regarded as larger scale rhythms and which can be correlated throughout the English Kimmeridge Clay.

The various lithologies are made up of a relatively small number of siliciclastic, bioclastic, biogenic and chemogenic components. The clastic materials are clay minerals (mostly illite and kaolinite), quartz, calcium carbonate in the form of microscopic and macroscopic shell debris and phosphatized fossil debris. The biogenic component consists mostly of calcareous fossils and of kerogen composed largely of dia-genetically modified lipids probably derived in part from marine algae such as dinoflagellates. Diagenetically formed pyrite, phosphate and cementstone concretions make up the relatively small chemogenic component. The typical composition of some of the commoner Kimmeridge Clay lithologies can be summarized as follows:-

(i)   dark grey mudstone - clay minerals 45 to 65%, quartz 10 to 30%, calcium carbonate 5 to 20% depending upon shell content, kerogen < 1%

(ii)   medium grey mudstone - clay minerals 35 to 55%; quartz 10 to 15%; calcium carbonate 20 to 35%; kerogen < 1%

(iii) pale grey mudstone - clay minerals 25 to 45%; quartz 8 to 15%; calcium carbonate 25 to 55%; kerogen < 1%

(v) oil shale - clay minerals 20 to 40%; quartz 10 to 15%;
calcium carbonate 10 to 25%; kerogen 10 to 45%

The two most distinctive Kimmeridge Clay lithologies that can be recognised in weathered sections at outcrop in Norfolk are muddy limestones and oil shales. Persistent tabular beds or closely spaced doggers of limestone occur in the mutabilis (Bed 18), eudoxus (Bed 30), scitulus (Bed 37), hudlestoni (Bed 44) and pectinatus (Bed 48) zones. Each of these can be recognised on the basis of either fauna or lithology. The Bed 18 limestones commonly enclose large Aulacostephanus with smooth body chambers (A. mutabilis (J. Sowerby)) and small, finely-ribbed forms (A. eulepidus (Schneid)); the Bed 30 limestones and adjacent mudstones commonly contain coarsely-ribbed Aulacostephanus of the eudoxus group, the large perisphinctid Propectinatites?, large forms of the oyster Nanogyra virgula (Defrance) and common serpulids. The limestones in Beds 37, 44 and 48 all contain similar pectinatitid and bivalve faunas but the first is a tabular, calcite-cemented oil shale, the second consists of large doggers and lies only 1 to 2 m above thick oil shales with Saccocoma (Bed 42) and the third only occurs beneath The Wash.

Limestone doggers occur in Beds 1, 4, 7, 8, 13, 15, 17, 23, 24, 34 and 40 but are too widely spaced to be confused with the five persistent horizons described above except in very small sections where the spacing of the doggers cannot be determined.

Thin seams of oil shale occur throughout the eudoxus to pectinatus zones inclusive but are concentrated in five main oil shale-rich

bands in the eudoxus (2), elegans, hudlestoni and pectinatus zones.
A borehole at North Runcton [TF 6404 1624], drilled to examine the
oil shales, proved 80 seams ranging from 1 to 47 cm in thickness
(Gallois 1978). At outcrop the oil shales are usually much altered
due to the interaction of the weathering products of their high pyrite
content with their shelly fauna. When thus weathered they are usually
fissile, parting along bedding planes encrusted with secondary
gypsum [Ca $SO_4.2H_2O$] crystals and powdery natrojarosite [Na Fe_3 $(SO_4)_2$
$(OH)_6$.]. At some levels the oil shales are rich in phosphatized fish
debris and faecal pellets and this may be the source of phosphorus
that enables the brilliant blue mineral vivianite [Fe_3 $(PO_4)_2.8H_2O$]
to form in some of the weathered oil shales. The organic (kerogen)
part of the oil shales is surprisingly resistant to weathering and where
the oil shale is only sparsely shelly it can be split to reveal well
preserved calcareous and pyritic fossils.

The oil shale seams cannot be distinguished from one another
except by their faunas and, even then, in only broad terms. The oil
shales of the eudoxus Zone are rich in the small smooth or finely
ribbed, keeled ammonite Amoeboceras (Nannocardioceras) and also contain
Aulacostephanus, Aspidoceras, Amoeboceras (Amoebites), Laevaptychus and
Sutneria. Those in the elegans to pectinatus zones contain forms of
Pectinatites that are difficult to identify as crushed or incomplete
specimens. The hudlestoni Zone oil shales are distinguishable at one level
(Bed 42) by the presence of abundant pyritized plates of Saccocoma.

The Kimmeridge Clay contains a rich marine fauna dominated by
bivalves and ammonites but with gastropods, belemnites, brachiopods,

serpulids and fish, reptile, crustacean and plant debris common at selected levels. Crushed but otherwise well preserved ammonites are common throughout the sequence and because they occur in assemblages of rapidly evolving forms provide an excellent basis for a zonal scheme. The ammonite faunas are dominated by perisphinctids, the zonal scheme being based on species of Pictonia, Rasenia, Aulacostephanus and Pectinatites (Fig. 2). Other ammonites are common in the Rasenia and Aulacostephanus zones, notably Amoeboceras, Aspidoceras and Sutneria, but in the overlying Pectinatites zones no ammonite other than Pectinatites has been recorded from Norfolk. Gravesia, which has been collected at this stratigraphical level in Dorset and Surrey and forms an important link with Kimmeridgian sequences elsewhere in Europe, has yet to be recorded in the county. The highest part of the Kimmeridge Clay, characterised by species of Pavlovia and Virgatopavlovia, is absent in Norfolk due to uplift and erosion in the late Jurassic but phosphatized, water-worn fragments of these ammonites occur in the basal pebble bed of the overlying Sandringham Sands.

Most of the non-ammonite macrofauna of the Kimmeridge Clay is made up of long-ranging taxa but some of these can be stratigraphically useful where they make a sudden appearance or where they occur in great abundance over a small vertical range. A number of faunal marker bands of this type have been identified in boreholes in Norfolk; a few have been recorded at outcrop and others might be expected to occur in the spoil from temporary excavations and drains.

Amongst the bivalves the small oyster Nanogyra virgula ranges from the mutabilis to the wheatleyensis zones but is especially abundant in

Norfolk in three thin beds, two in the _eudoxus_ Zone and one in the

basal _wheatleyensis_ Zone. The highest band crops out or is overlain

by only thin Recent deposits in the area between Wiggenhall and Southery

and might be expected to occur in excavations there. In the Upper

Kimmeridge Clay of the same area the bivalves 'Lucina' _miniscula_ Blake,

Protocardia _morinica_ (de Loriol), _Astarte_ and small oysters and the

inarticulate brachiopods _Discinisca_ and _Lingula_ are common but are not

diagnostic of any particular stratigraphical level.

Crinoids are rare in the Kimmeridge Clay except at one level in

the _mutabilis_ Zone where _Pentacrinus_ columnals are abundant and at four

levels, in the _eudoxus_ (2), _autissiodorensis_ and _wheatleyensis_ zones,

where pyritized plates of the tiny free-swimming _Saccocoma_ occur in great

abundance. Each of the _Saccocoma_-rich bands occurs in oil shale and,

when fresh, the brass-coloured plates stand out in marked contrast to the

dull brown of the oil shales. The highest of the four bands has been

recorded at outcrop at Setchey and Downham Market. At both localities

the pyrite is largely destroyed by weathering but the shape of the _Saccocoma_

plates has been preserved in secondary gypsum overgrowths.

Rhynchonellid brachiopods are common in the muddy siltstones

(Beds 15, 17 and 24) in the _mutabilis_ and _eudoxus_ zones. These beds

are covered by thick drift deposits everywhere in Norfolk but loose

blocks of the siltstones have been recorded from the local boulder clay.

Rhynchonellids have also been recorded from the _wheatleyensis_ Zone

(Bed 41) in Norfolk but not in sufficient numbers for their stratigraphical

distribution to be accurately known.

Details of sections

There is no natural exposure of Kimmeridge Clay in Norfolk at the present time nor is there any working clay pit that exposes any part of the formation. However, fragments of the more resistant Kimmeridge Clay lithologies, notably oil shales, cementstones and some of the harder mudstones, occur in the spoil at a number of localities where sections formerly existed, mostly at the sites of engineering works. When compared with the standard sequence shown in Fig. 2 these spoil fragments can provide useful stratigraphical information. The positions of the sections and their relationship to the Kimmeridge Clay outcrop and its subcrop beneath drift deposits are shown in Fig. 3. Beds 30 to 33 are present at shallow depths beneath Recent deposits in west Norfolk and should occur from time to time in drain spoil: Beds 34 to 47 crop out and will become available for study in temporary excavations.

In addition to the localities listed below Rose (1835) and Whitaker et al. (1893) recorded Kimmeridge Clay in brick-pits at Denver, Fordham, Watlington, West Winch and Shouldham Thorpe, but no description or material has survived from any of these sections. The last named locality is sited on boulder clay which rests at depth on Sandringham Sands and the brick pit, at Foddestone Gap [TF 652 089], was interpreted by Reid (in Whitaker et al. 1893, p. 63) as being in a 50 ft-thick erratic mass of Kimmeridge Clay within the boulder clay.

1. South Wootton; a small excavation dug for an electricity sub-station in 1972 at Chapel Lane, South Wootton [TF 6405 2318], close to the junction with the Sandringham Sands, proved about 1 m of weathered mudstone and

oil-shale with fragments of finely-ribbed pectinatitid ammonites
(probably Bed 46 or 47).

2. North Lynn; spoil from a 2 m-diameter sewerage tunnel which passed
beneath the River Great Ouse at North Lynn [TF 604 227] in 1972 included
large doggers of densely calcite-cemented oil shale together with
mudstones and thin oil shales. The cementstone was a single impersistent
bed that followed the axis of the tunnel for most of its length. The
mudstones and oil shales contained 'Lucina',Protocardia, Lingula and
pectinatitid ammonites and suggest that the stone band is that which
marks the base of the scitulus Zone (Bed 37) in Norfolk.

3. Fairstead Estate, King's Lynn; spoil from sewerage trenches [TF 642 194]
dug for a new housing estate in 1966 showed the basal bed of the Sandring-
ham Sands underlain by softened dark grey clay with thin oil shales.
These shales included fragments of a soft, very pale brownish grey,
coccolith-rich limestone with Pectinatites (P.) eastlecottensis (Salfeld)
(base of Bed 46).

4. Fenland Flood Relief Channel; between Lynn sugar beet factory
[TF 6050 1730] and St. Germans Bridge [TF 6084 1571] the spoil from
the channel shows its floor to have been cut entirely in Upper Kimmeridge
Clay. Loose doggers of cemented oil shale (Bed 37) occur near the
sugar beet factory. Between St. Germans Bridge and Wiggenhall St.
Mary Magdalen railway bridge [TF 6000 1025] the channel is cut in
glacial deposits. From there southwards the floor of the channel is
again entirely in Kimmeridge Clay. Lower Kimmeridge Clay, consisting
of oil shales with abundant Nannocardioceras (probably Bed 32 or 33),
comes to the surface in a gentle anticline between Wiggenhall St. Mary

Magdalen and Stowbridge [TF 605 070]. These are the oldest strata
recorded at the surface to date in Norfolk.

Successively higher levels of the Upper Kimmeridge Clay can
be recognised in the spoil between Stowbridge and Downham Bridge
[TF 601 033]. At this last locality the following section is exposed
in the east bank of the channel for some 200 m north of the bridge at
times of low water:

Bed 44:   Pale grey, uniform, almost barren clay, softened and
weathered; discontinuous line of large cementstone doggers
1.0 m above base; sharp base to unit   ....1.40 m

Bed 42:   Oil Shale, shelly, fissile, deeply weathered with
rotted bivalves and ammonites and pyritized Saccocoma; inter-
bedded with dark grey fissile shelly clays   ......cl.l m

The combined presence of Saccocoma and Pectinatites in the oil
shales is diagnostic of Bed 42 and the overlying pale grey clays and
cementstone of Bed 44. A similar, but less well exposed section,
occurs in the north bank of the Cut-Off Channel at Fordham [TL 607 996].
This latter locality has yielded a specimen of Rhynchonella subvariabilis
Davidson (Sedgwick Museum, Cambridge) one of the few records of an
articulate brachiopod in the Upper Kimmeridge Clay in Norfolk.

The Upper Kimmeridge Clay spoil from the Flood Relief and
Cut-Off channels between Downham and Fordham has also yielded numerous
ichthyosaur and plesiosaur vertebrae (much prized as ash-trays by

local farmers) and fragmentary reptilian bones. An almost complete

icthyosaur skeleton from Stowbridge has been described as a new form,

Grendelius mordax, by McGowan (1976). Beds 40 to 46 were probably

exposed at the time of excavation of the Cut-Off Channel between

Downham Market and the junction with the Sandringham Sands near Snowre

Hall, Fordahm [TL 631 996]. Only Beds 42 and 44 can still be recognised

with confidence.

5. Setchey; contemporary photographs of the small opencast pit dug

for oil shales in about 1920 at Setchey [TF 6268 1452] suggest that it

was in an oil shale-rich band (Bed 42) in the wheatleyensis Zone and

that the overburden included the pale calcareous mudstones and

cementstones of Bed 44. This suggestion was supported by the observations

of the late Dr. J. Pringle who obtained samples from the pit in 1917 via

a testing works at Chiswick. The fauna of the oil shales included

Saccocoma and pectinatitid ammonites and enabled Pringle (unpublished

MSS 1919) to correlate the Setchey seams with the Blackstone of Dorset.

In 1975 IGS made a temporary excavation in the northern side of the pit

to examine the weathering profile of the shales and to obtain samples

for chemical analysis. The following section was measured:

Pleistocene deposits: cryoturbated flint
    gravel, ferruginous sand and sandy clay
    (derived largely from the Kimmeridge Clay)   ....1.9 m

Kimmeridge Clay Bed 44; pale and medium
    grey, deeply weathered calcareous clays with
    a line of cementstone doggers in lower part
    of bed; shelly in part with rotted bivalves
    and ammonites; sharp planar contact with
    bed below disturbed by burrows   ....1.6 m

> Bed 43; very dark grey, apparently barren
> clay softened by weathering ....0.16 m
>
> Bed 42; oil shale, dark brownish grey with
> brown streak; fissile, shelly with
> abundant 'Lucina' miniscula and rarer
> Protocardia, small oysters, Discinisca
> and fragments of Pectinatites; fish debris
> and faecal pellets locally common;
> Saccocoma abundant at one level; inter-
> bedded in 5 to 30 cm-thick seams with
> sparsely shelly dark grey clays ....1.7 m seen

The oil shale were well jointed and yielded large quantities of water that made it impossible to deepen the excavations.

The oil shales seams which were worked in the Setchey opencast pit crop out in the banks of the Puny Drain [TF 626 145] about 100 m west of the pit. There is currently no exposure but large amounts of deeply weathered oil shale are present. Most of the calcareous fossils and all the pyritised fossils in the shale are completely rotted.

In his account of the oil shale workings Forbes-Leslie (1917, p. 18) referred to a mine [TF 625 145] that was overcome by an inrush of oil-covered water. It is unlikely that this mine ever worked oil shale since it seems to have been abandoned for financial reasons during the construction stage. The layout of the mine, as shown on the Ordnance Survey 25-inch scale map of 1925, consisted of two shafts and an engine house. One of these shafts was open until about 1970 when it was back-filled by the local landowner who measured the depth at that time as approximately 15 m. The small amount of spoil still present consists largely of dark grey shelly mudstone with thin oil shale seams. The faunal assemblage, mostly 'Lucina', Protocardia and Pectinatites fragments, together with the depth of the shaft, suggests that the

seams encountered were those of the _elegans_ Zone (Bed 36).

Forbes-Leslie (1917, p. 16-17) recorded at least three 6 ft-thick oil-shale seams in the Kimmeridge Clay of the Setchey area but no such seam has subsequently been recorded.

6. Stowbridge; extensive workings in Pleistocene flint gravels at Stowbridge [TF 614 073] have revealed the irregular weathered surface of the Kimmeridge Clay. Spoil from the clay includes pale grey calcareous mudstones, cementstone doggers and thick oil shale seams. This combination of lithologies, when taken in conjunction with the nearby Flood Relief Channel sections, indicates the presence of Beds 42 and 44.

7. Downham Market; Whitaker _et al._ (1893, p. 47) recorded a brick-pit in the Kimmeridge Clay close to the railway station [TF 604 030] where 30 ft (9 m) of clays were worked above a floor of cementstone septaria. The section is now overgrown but the position of the pit suggests that it worked the calcareous clays of Bed 44 and that the cementstone in its floor is the same as that which crops out in the Flood Relief Channel at Downham Bridge. A similar cementstone, probably the same band, was noted by Whitaker et al. (loc. cit.) in the foundations of the nearby gasworks.

8. Southery; Rose (1835, pp. 174-5) recorded a brick pit at Southery [probably TL 617 958] and noted that it exposed 13 ft (4 m) of 'brick-earth' underlain in the floor of the pit by a 2 to 3 in-thick seam of inflammable shale. The bulk of the pit is in pale grey clays with cementstone doggers (Bed 44) and is at the same stratigraphical level as locality 7. It was presumably this calcareous clay that gave rise

to the yellow stock brick that is much in evidence in the Victorian
and Edwardian parts of Downham Market and Southery. The underlying oil
shales are those of Bed 42. Recent excavations for the Southery Bypass
[TL 616 946] showed pale grey calcareous clays (Bed 44) overlain by
chalky boulder clay rich in local Upper Jurassic and Lower Cretaceous
debris. Fitton (1836, p. 316) collected two characteristic Lower
Kimmeridge Clay fossils at Southery, the large flat oyster Deltoideum
delta (Wm. Smith) and Laevaptychus, the aptychal plate of Aspidoceras.
D. delta is known only from the Ampthill Clay and the basal beds of the
Kimmeridge Clay: Laevaptychus only from the mutabilis to autissiodorensis
zones (Beds 18 to 33) of the Kimmeridge Clay. The oldest Kimmeridge
Clay at outcrop on the 'island' of Southery is in Bed 42 and could not
be the source of these fossils. However, both fossils have thick
calcitic shells and are common in the boulder clay of west Norfolk.
9. Southery; spoil from the foundations of a new (1977) pumping station
at the junction of the Engine Drain and the Great Ouse [TL 6128 9318]
included cementstone doggers and mudstones with fragments of Aulacoste-
phanus and abundant Nanogyra virgula (probably Bed 30). The Recent
deposits of this part of Southery Fens are thin and many of the deeper
drains lying on either side of the Great Ouse have cut into the weathered
upper surface of the Kimmeridge Clay.

Conclusions

The stratigraphy of the Kimmeridge Clay beneath Fenland and in
its subcrop beneath the Sandringham Sands in Norfolk is known in detail
from continuously cored boreholes. By contrast, little is known about

the stratigraphy at outcrop other than the stratigraphical positions of a small number of marker bands recorded in old brick-pits and temporary excavations.

Only the upper part of the Kimmeridge Clay crops out in Norfolk, but even within this limited sequence there are stratigraphical problems that cannot be solved by boreholes alone. Because of their small diameters (mostly 80 mm to 110 mm) borehole cores are unsuitable for determining the stratigraphical ranges of the less common parts of the faunal assemblage and those species that are large in relation to the core-diameter.

The distribution of rhynchonellid brachiopods in the Upper Kimmeridge Clay is a good example of the problems associated with the rarer elements of the fauna. _Rhynchonella_ _subvariabilis_ Davidson has been recorded at approximately the same stratigraphical level (Bed 41) in two boreholes in Norfolk. Other boreholes in the county that have penetrated the same bed have failed to yield brachiopods and it is not known whether the specimens collected represent isolated occurrences or whether they are part of a widespread marker band in which the brachiopods are thinly distributed. The pectinatitid ammonites upon which the zonation of the Upper Kimmeridge Clay is based are mostly greater than 75 mm in diameter (some 350 mm diameter) and complete specimens are rare in borehole cores. Their identification at species level depends, in most cases, on counting the number of ribs on complete, mature specimens. In consequence many species are known from only a single identifiable specimen (see Gallois and Cox 1974, Fig. 3 for examples). The stratigraphically important ammonite _Gravesia_ has yet to be recorded in

Norfolk even though the beds in which it would be expected to occur have been penetrated by numerous boreholes and despite the fact that these beds crop out in the Stowbridge area.

An extreme example of large fossils in the Kimmeridge Clay are the ichthyosaurs and pleisosaurs. Fragments of these marine reptiles are common in the spoil from most excavations in the formation but their stratigraphical distribution in the area is completely unknown.

The stratigraphical sequence summarized in Fig. 2 should not therefore be regarded as a final answer, but merely as a temporary model that enables new data to be interpreted and incorporated into future better, but probably equally temporary, models. A comprehensive collection of lithological and faunal specimens from the Kimmeridge Clay of Norfolk is housed in IGS collections in London. These can be consulted by appointment. In addition, the author or his colleagues would be pleased to attempt to identify any specimens collected from temporary exposures in Norfolk. Good hunting.

KIMMERIDGE CRAWL: FIELD TRIP TO WEST NORFOLK, SUNDAY, 9 SEPTEMBER 1979

B.M. FUNNELL*

Four cars and eight persons starting from the Norwich area, and six cars and more than a dozen members and friends from the Kings Lynn area, met at 10.15 am. at Denver Sluice for a day of collecting and clambering over Kimmeridge Clay exposures.

Activities started in earnest near Southery pumping station (TL 612932) where fresh spoil, including Kimmeridge Clay, had recently been taken from the Southery Main Drain alongside Sedge Fen road. Vertebrae, bivalves, oil shale and pieces of "beef" were found. More oil shale was found freshly excavated at the W side of the White Bridge (TL 616944), but freshly dumped foundation for the Southery by-pass that takes off westward from the old line of the A10 at this point had been rolled during the week and only a few of the large Pectinatites in it could still be seen.

Lunch was taken beside the river Wissey at Hilgay and the first stop in the afternoon was beside Downham bridge (TF 601033), where the large cementstone doggers of Bed 44 in the Upper Kimmeridge Clay could be seen in the E bank of the Relief Channel immediately N of the bridge. Mr. J.E. Clarke, Clerk to the Southery Internal Drainage Board then took us to see new excavations at Stow pumping station (TL 598057) where some really oily shale had been brought to the surface with some large ammonite specimens in it. There were also some interesting blocks showing patches of the brilliant blue mineral vivianite scattered around. More ammonites, an occasional vertebra, and good septarian nodules and cone-in-cone structure were found on the spoil from the freshly excavated 16 foot Drain nearby (extending towards TL 595055).

*School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ

The party continued to Stowbridge, where, in spite of the high water level, ammonites were obtained from some more cohesive blocks on the W bank just S of the bridge over the Relief Channel (TF 605 070).

Time prevented the party continuing to view the old shale workings at Setchey (TF 626 146), but it was generally agreed that the collecting and the fine warm September day had been enjoyed by all. We are all grateful to Ramues Gallois and members of the West Norfolk group who provided notes to help plan the day and to John Clarke, who guided us around the Internal Drainage Board's works.

BMF

FIELD MEETING AT BRAMERTON COMMON, SEPTEMBER 3rd 1978.

P. CAMBRIDGE*

The Norwich Crag at Bramerton has attracted a great deal of attention since the ealiest days on account of the rich fauna of molluscs, fishes and mammals, and in recent years the foraminifers and pollen. It was visited by the great William Smith and specimens from this area were illustrated in Sowerby's "Mineral Conchology". At the present day remains of two old pits can be traced, Blake's Pit (TG 298060) to the east and the Common Pit (TG 295060) to the west. Traces of shelly material were seen in house foundations as far as the "Wood's End". To the west of this the Crag beds appear to have been cut out by Glacial or post-Glacial beds, as shown in the gas pipeline trench, a few hundred yards to the west. This trench was cut from river level to the top of the hill with no trace of Crag. Beds with a similar fauna to that at Bramerton occurred in excavations for the new sewage plant at Whitlingham but on examination were seen to be redeposited material and no Crag was seen in situ, so the disturbance of the Crag beds continues at least as far as the sewage plant. A little further to the west the Crag is again seen in the Great Pit, close to the bend in the river a Whitlingham, and here the surface of the Chalk is much higher and the shelly sands reduced in thickness. On the other side of the river, an old pit at Postwick Grove exposes some Chalk, and Crag shells are thrown out by rabbits. Some Crag was visible in 1951 but the pit is now much overgrown and infilled. However, examination of shells from a disturbed slope showed a fauna similar to that at Bramerton.

The first description of the Bramerton area seems to be that given by Richard Taylor (1823) who also gives a delightful sektch of a pit at Bramerton, probably that now known as the Common Pit, with a detailed section and list of species. The area was described slightly more fully by S. Woodward (1833) and since this work is now rare the description may be worth repeating:

*258 Bluebell Road, Norwich.

"At Bramerton, the shells may be traced in the bank on the right hand

for a quarter of a mile as you approach the Wood's-end house. The

cliff is situated about a quarter of a mile below the house by the river

side: and, about two hundred yards down the river, a thick bed has been

cut through to enlarge a cottage garden."

It would appear that at this date the river ran closer to the side of the

hill and that much of the present Common is made ground. A list of about 92

species is given and two plates of Crag fossils are illustrated including

examples of the monstrosities of Nucella and Littorina and some fish bones

later described by Agassiz, although the latter's illustrations are far

inferior to those of S. Woodward. Extensive collections, now in the Castle

Museum, were made by a local geologist, James Reeve, who communicated a list

of 111 species to the Norwich Geological Society (1878). His list is divided

into an upper and lower bed for Bramerton Common but gives no indication of

horizons for Blake's Pit.

A brief description of Blake's Pit is given by Wood (1865) and Wood and

Harmer (1872) in which the lower bed is described as Fluvio-Marine Crag, with

a marine facies above, the upper part of which was called the Chillesford

Shell Bed. In the Survey Memoir, H.B. Woodward (1882) gives some notes and a

section at Bramerton Common plus a brief description of Blake's Pit, which

appears less accurate than the earlier description by Wood.

There then appears to be a considerable gap in research on the area of

over half a century, until 1958 when a section in the Common Pit was re-

excavated by Funnell (1961) during an investigation of the foraminiferal

fauna. At a meeting of the British Association (1961) the present author led

a party to examine this new section but by an accident of navigation the party

actually examined Blake's Pit. The only exposure at that time was at the top

of the pit where a badgers sett had exposed very shelly Crag. Typical

monstrosities of Nucella and Littorina were collected. On subsequent visits

this bed was extensively sampled by the author and visited by a number of

parties, extending the small exposure of the shell bed. In 1974 Blake's Pit

was re-excavated by the Geological Society of Norfolk and the lower part of the section exposed for the first time for many years. The warmer aspect of the fauna in the lower beds was confirmed, as well as the wealth of non-marine mollusca. The latter included one new genus, not hitherto recorded from northern Europe, Parmacella. The presence of small examples of derived Pliocene fossils was also noted.

A notable feature of the description of sections in the Bramerton area is the variation in thickness of the Crag given by different authors (see Fig. 1). In Blake's Pit, which does not show the full sequence, there is a maximum thickness of 27 feet (Cambridge/Markham). In the Common area measurements varied from just under 40 ft (Funnell)? to just under 50 feet (Taylor, 1824) and even 60 ft (Woodward,1833).Taylor also recorded three shell beds where other authors record two. The excavation in 1978 was intended to investigate these differences and also to see if the shell bed in Blake's Pit with its unusual fauna, could be traced into the Common area.

The new section was dug at a point judged to be close to that made by Funnell and the first 15 feet corresponded closely to his published section (Zone BIII), with no visible fossils. At this depth a shell bed was reached with a very pebbly matrix. Funnell and Woodward record an Upper Shell Bed with a sandy matrix; Taylor records a pebbly bed. These differences probably represent a lateral variation in lithology, common in such shallow water deposits. Most of the published sections agree that below the shell bed are a series of sands with few or no shells. Similar sands were excavated for a further 12 feet but at this depth the loose scree through which the trench was being dug commenced to collapse. Despite intense efforts to continue the short distance needed to expose the next shell bed, the collapse became too general and that part of the dig had to be abandoned. A small trench dug a little to the right also exposed the pebbly facies of the Upper Shell Bed and samples were taken from both sites. An attempt to expose the chalk at the base of the pit was also unsuccessful. A seven foot deep trial hole showed only
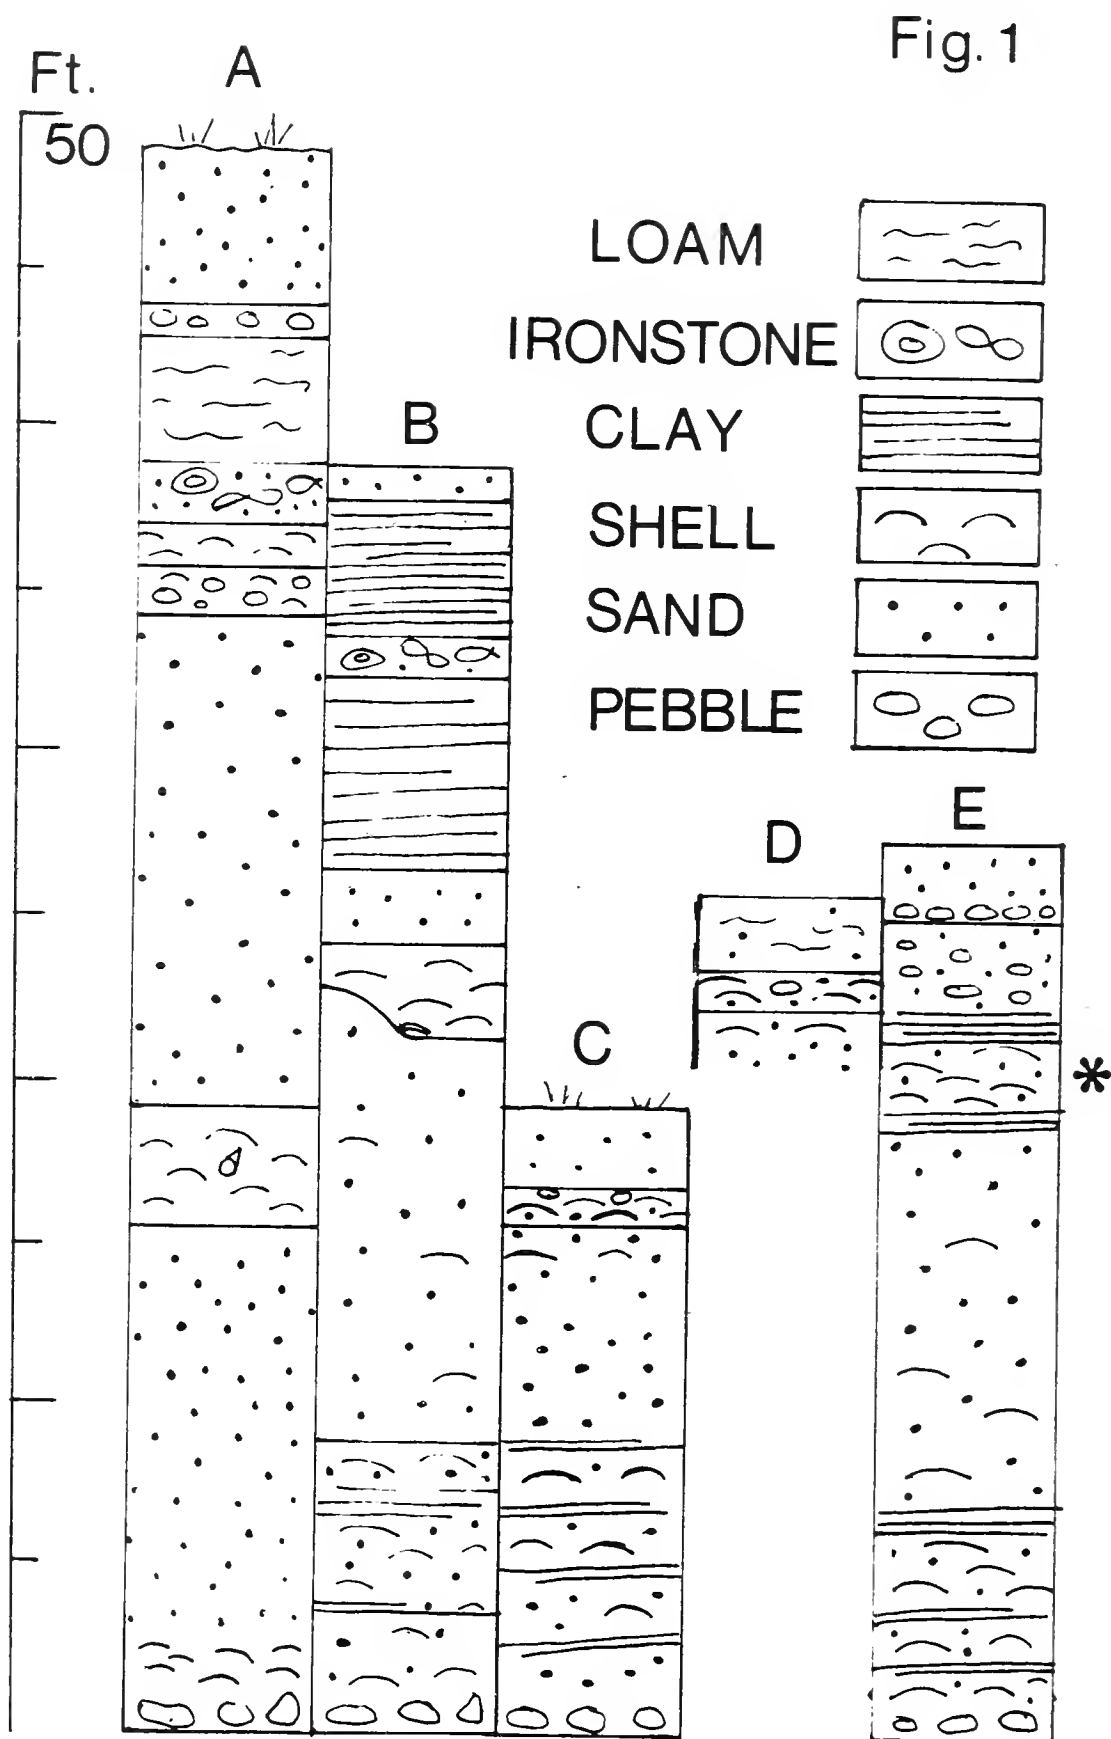

Sections in the Crag at Bramerton according to various authors, somewhat simplifie

    A. Common Pit after R. Taylor

    B. Common Pit after B.M. Funnell

    C and D. Blake's Pit after P. Cambridge

    E. Common Pit after H.B. Woodward, with (*) Zone of Astarte borealis.

disturbed material although the surface of the chalk should actually stand higher than the base of the pit.

The exposure of the lower part of this pit is very desirable but owing to the height of the original face and the consequent thickness of loose scree, this will be a major task unless a mechanical excavator is used.

Palaeontology of the Upper Shell Bed

Bivalves predominated, especially Macoma obliqua and to a lesser extent M. calcarea, Yoldia myalis, Mya sp and Astarte borealis. This would be the 'Zone of A. borealis' of earlier authors. Like the Upper Shell Bed of Blake's Pit there is a northern element in the molluscs but there are also considerable differences. No distorted or monstrous forms of Nucella and Littorina were seen. The Nucella were of the short rounded form characteristic of recent open coasts whereas in the Upper Shell Bed of Blake's Pit elongate forms associated with estuaries at the present day dominate. The change in shape of Nucella, the increase in the number of teeth of rays and other fishes, and the decrease in the number of non-marine shells in the Upper Shell Bed of the Common Pit all point to a change in this area from enclosed estuarine deposits to those of a more open shore line.

Derived Chalk fossils include belemnite guards, echinoid spines, a
rhynchonellid etc.

Among the rock and mineral types were flint pebbles (dominant), bored chalk
pebbles, jasper, chalcedony, milky quartz, a terminated crystal of rose
quartz, and quartzites.

Key to list.

X = present

F = present only as fragments

Below five specimens the acrual number of examples is given.

Note

In order to achieve consistency Imperial measures have been used
throughout since most of the original sources quoted are in feet and inches.
Some authors measured to the nearest six inches, others to the nearest foot.
(I foot equals 0.305 metres).

<u>Mon. Pal. Soc.</u>

Woodward, H.B. 1882 The Geology of the Country around Norwich. <u>Mem. Geol. Surv.</u>

Woodward, S. 1833 An Outline of the Geology of Norfolk, Norwich.
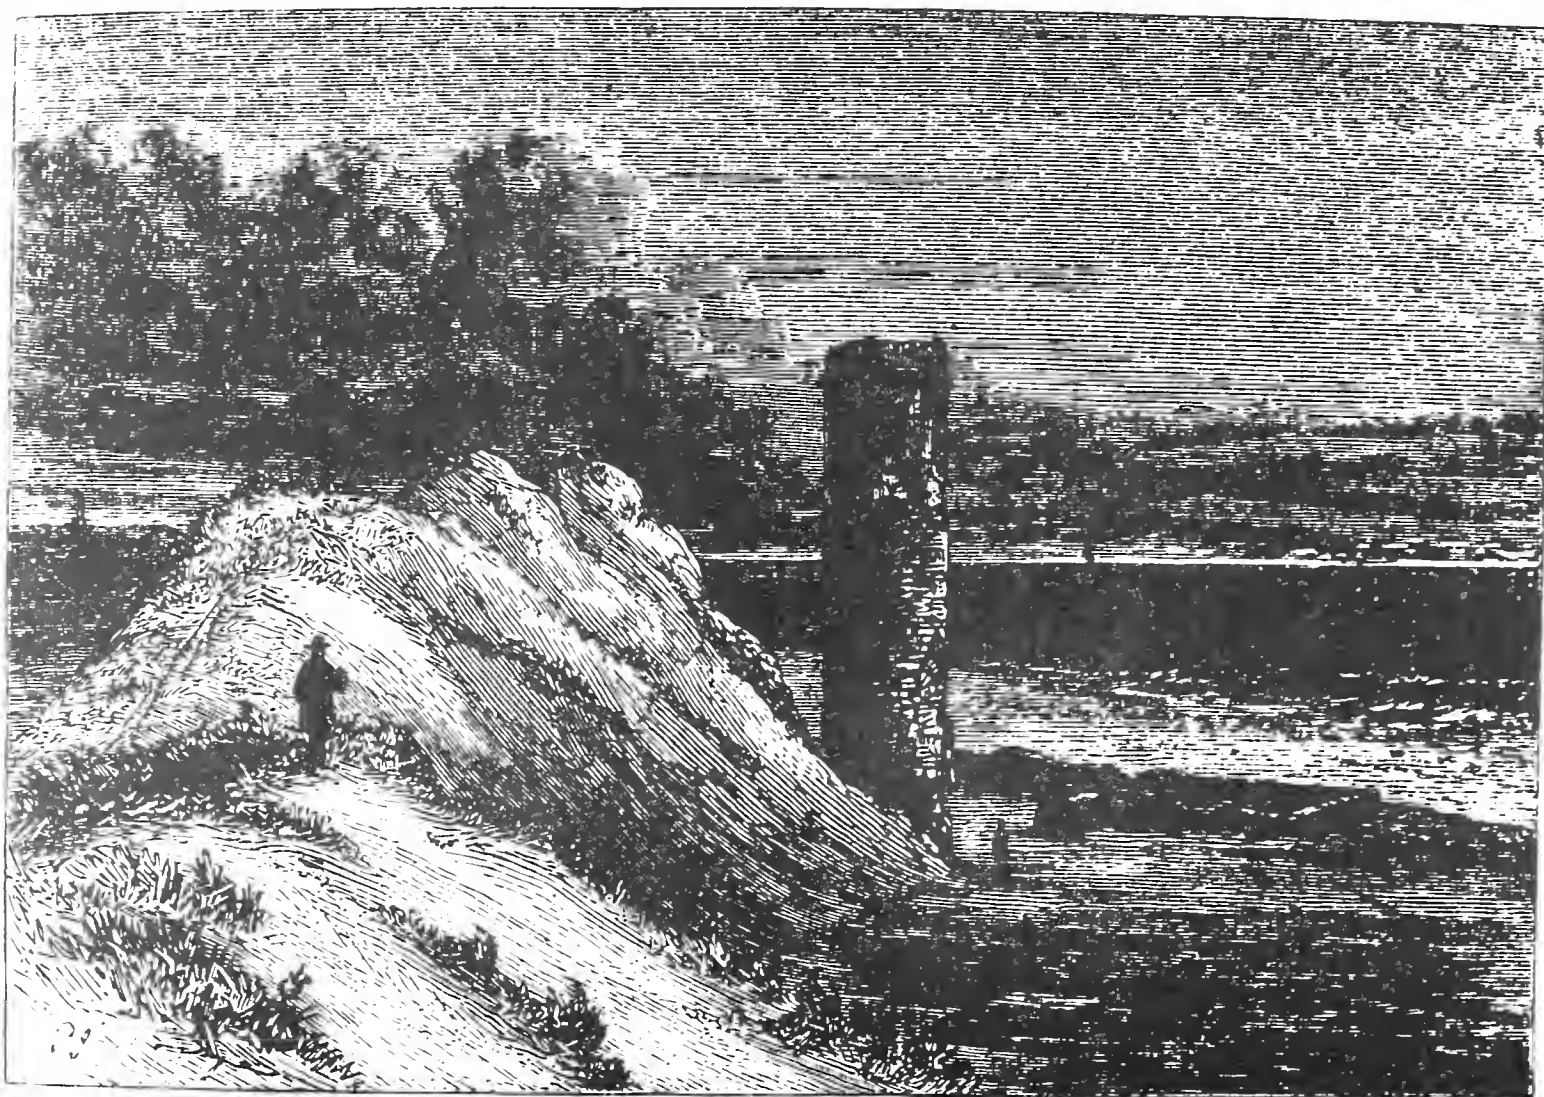

"Eccles Tower as it appeared after the storm of November 1862, from

a drawing by Rev. S.W. King". Taken from Fig. 43 (p. 515) of Lyell's

"Principles of Geology", 1867 edition, (see cover of this Bulletin).

It seems that the problems of coastal erosion in parts of East Anglia

have been recognised for a long time for "as early as 1605 the inhabit-

ants (of Eccles) petitioned James I for a reduction of taxes, as

300 acres of land and all their houses, some fourteeen, had then

been destroyed by the sea" (op. cit. p. 513).

SECRETARY'S REPORT FOR 1978

In addition to the summer field meetings the programme consisted of
five evening lecture meetings, the Annual General Meeting and two
afternoon "Collectors' Sessions" as follows: January, Dr. A.J.
Stuart, 'Recent Research on Forest Bed Mammals';February, A. Collectors'
Session for identification of specimens and Dr. J. Guest, Extra
Terrestrial Geology; March, Mr. P.J. Lawrence, 'Bones for Beginners';
October, Mr. R. Markham, 'A Review of Some Recent Crag Exposures in
East Anglia';November, The Presidential Address by Dr. G.S. Boulton on
'The Glaciation of the North Sea Basin'; December, a Collectors'
Session and the A.G.M. which was followed by a showing of slides taken
at field meetings during the year and a guided tour behind the scenes
at the Museum.

The talk by Dr. Guest was given as a joint lecture for the G.S.N. and
the Norwich Astronomical Association and was held at the University.
All other meetings were at the Castle Museum.

The innovation of the Collectors' Sessions held on Sunday afternoons
at the Castle Museum was made possible by Peter Lawrence and thanks
are due to him for suggesting the idea and providing the facilities
so that members of the public as well as G.S.N. members could bring
specimens for identification or showing to others. I hope that these
events might become a regular part of the Society's programme in future.

There were three committee meetings during the year.

This year sees the end of a three year stint on the Committee by both Mrs.
Evans and Mr. Peake. I would like to thank them very much for their
help and advice and for giving up their valuable time to attend.

This year also saw the subscription being raised to £1.50. However this
was the first raise that has occurred for some years and although it was
regrettable I think it was fairly generally agreed that it represents good
value in that the Winter Lecture Meetings and the Summer field meetings
together with the Bulletin offer members a fairly wide range of interest
throughout the year. I hope however that as always people will let one or
the other committee members know of areas or subjects of interest which
could be covered in future.

The committee for 1979 is as follows:

Secretary:	Dr. C.J. Aslin
Treasurer:	Mr. P.G. Cambridge
Editor:	Dr. P.N. Chroston
Field Meeting Secretary:	Mr. P.J. Lawrence
Committee Members	Mr. D.J. Allen
	Mr. N.E. Dean
	Mrs. A. Horsfield
West Norfolk Member:	Mr. A.G. Barnes

Christopher J. Aslin,   December 1978.

EDITORIAL NOTE

The Bulletin of the Geological Society of Norfolk seeks to provide an opportunity for the publication of research papers, notes, or general articles which are relevant to the geology of Norfolk in particular, or to East Anglian geology in general. The Society is also prepared to consider articles of general geological interest for publication, but normally they will be expected to include some local relevance. There are no restrictions on subject matter (apart from regional significance) and no formal restriction on length. We welcome full length research papers, short notes, and correspondence. All papers are normally refereed.

Potential contributors should note that we prefer manuscripts to be submitted in typewritten copy, and it would be helpful if the style of the paper in terms of capitalization, underlining, punctuation etc., would conform strictly to those used in the Bulletin. The reference list is the author's responsibility alone and should be checked carefully.

Illustrations should be executed in thin dense black ink line. Thick lines, close stipple or patches of black should be avoided as these tend to spread in the printing process employed. Original illustrations should, before reproduction, fit into an area of 225 mm by 175 mm. Full use should be made of the second (horizontal) dimension which corresponds to the width of print on the page, but the first (vertical) dimension is an upper limit only. Reproduction of photographs is normally possible provided there is adequate contrast.

All measurements in the script and illustrations should be in metric units.

I am happy to answer any queries concerning the suitability of a paper or any other editorial.

P.N. Chroston,
Editor,
University of East Anglia,
School of Environmental Sciences,
Norwich, NR4 7TJ.

CONTENTS

The Geological society of Norfolk exists to promote the study and knowledge
of geology, particularly in East Anglia, and holds monthly meetings
throughout the year. Visitors are welcome to attend the meetings and
may apply for membership of the Society. For further details write to
the Secretary: Dr. C.J. Aslin, University Library, University of
East Anglia, Norwich NR4 7TJ.

Copies of the Bulletin may be obtained from the Secretary at the address
given above. It is issued free to members.

The illustration on the front cover is taken from Figure 43 (page
514) of Lyell's "Principles of Geology", 1867 Edition, and shows the
"Tower of the buried church of Eccles, Norfolk, A.D. 1839". The view
shows "the inland slope of the hills of blown sand...with the lighthouse
of Hapisburgh, N.W. of the Tower, in the distance". Lyell showed that
in 1862 the sand dunes had moved inland, exposing the tower directly
to the sea (see p. 78 of this issue).
